CAMPBELL-WALSH
UROLOGY

CAMPBELL-WALSH UROLOGY

ELEVENTH EDITION

Editor-in-Chief

ALAN J. WEIN, MD, PHD (HON), FACS

Founders Professor of Urology
Division of Urology
Penn Medicine, Perelman School of Medicine;
Chief of Urology
Division of Urology
Penn Medicine, Hospital of the University of Pennsylvania;
Program Director, Residency in Urology
Division of Urology
Penn Medicine, University of Pennsylvania Health System
Philadelphia, Pennsylvania

LOUIS R. KAVOUSSI, MD, MBA

Waldbaum-Gardner Distinguished
Professor of Urology
Department of Urology
Hofstra North Shore-LIJ School of Medicine
Hempstead, New York;
Chairman of Urology
The Arthur Smith Institute for Urology
Lake Success, New York

ALAN W. PARTIN, MD, PhD

Professor and Director of Urology
Department of Urology
The Johns Hopkins School of Medicine
Baltimore, Maryland

CRAIG A. PETERS, MD

Professor of Urology
University of Texas Southwestern
Medical Center;
Chief, Section of Pediatric Urology
Children's Health System
Dallas, Texas

Notices

Knowledge and best practice in this field are constantly changing. As new research and experience broaden our understanding, changes in research methods, professional practices, or medical treatment may become necessary.

Practitioners and researchers must always rely on their own experience and knowledge in evaluating and using any information, methods, compounds, or experiments described herein. In using such information or methods they should be mindful of their own safety and the safety of others, including parties for whom they have a professional responsibility.

With respect to any drug or pharmaceutical products identified, readers are advised to check the most current information provided (i) on procedures featured or (ii) by the manufacturer of each product to be administered, to verify the recommended dose or formula, the method and duration of administration, and contraindications. It is the responsibility of practitioners, relying on their own experience and knowledge of their patients, to make diagnoses, to determine dosages and the best treatment for each individual patient, and to take all appropriate safety precautions.

To the fullest extent of the law, neither the Publisher nor the authors, contributors, or editors, assume any liability for any injury and/or damage to persons or property as a matter of products liability, negligence or otherwise, or from any use or operation of any methods, products, instructions, or ideas contained in the material herein.

Previous editions copyrighted 2012, 2007, 2002, 1998, 1992, 1986, 1978, 1970, 1963, and 1954.

Every 4 years or so, a small group of crazed individuals are privileged to convene and embark on a seemingly near impossible task—to improve upon what, a relatively short time ago, they had created as the gold standard textbook in urology. A week or so later, they emerge with a plan, each with their assignments for what they now are convinced is the best ever repository of total urologic knowledge. This group and this edition are no exceptions to this routine.

The four of us feel very honored and privileged to be a part of this tradition that began in 1954 with the publication of the first Campbell's Urology (then titled simply "Urology"), which consisted of 3 volumes in which 51 individuals contributed 2356 pages and 1148 illustrations. We are grateful to our current colleagues and friends who accepted the responsibility of producing anew the 156 chapters that comprise our text and acknowledge their expertise and the unselfish contribution of their time and effort.

Our gratitude to the chapter authors notwithstanding, we would like ultimately to dedicate this edition to two sets of individuals: One group includes our mentors in urology—those whom each of us separately admired and learned from, and whose educational and clinical achievements in various aspects of our field we have sought to imitate. Hopefully, they would or will be proud of our part in this 11th edition of the gold standard textbook. The greatest debt and thanks, however, are owed to our families, specifically our wives and children who were in the "line of fire" during the preparation of this edition. They deserve more than a medal or a copy of the book. So, to Noele and Nolan; to Julianne, Nick, Rebecca and Dree; to Vicky, Topper, David, Dane and Michael; and to Kathy, Jessica, Lauren, and Ryan, our thanks for your patience, understanding, and continued support. The good news is that you have a few years until the cycle begins again.

For myself and my fellow editors,
Alan J. Wein

Louis R. Kavoussi
Alan W. Partin
Craig A. Peters

CONTRIBUTORS

Paul Abrams, MD, FRCS

Professor of Urology
Bristol Urological Institute
Southmead Hospital
Bristol, United Kingdom

Mark C. Adams, MD, FAAP

Professor of Urologic Surgery
Department of Urology
Division of Pediatric Urology
Monroe Carell Jr. Children's Hospital at
Vanderbilt
Nashville, Tennessee

**Hashim U. Ahmed, PhD, FRCS (Urol),
BM, BCh, BA (Hons)**

MRC Clinician Scientist and Reader in
Urology
Division of Surgery and Interventional
Science
University College London;
Honorary Consultant Urological Surgeon
University College London Hospitals NHS
Foundation Trust
London, United Kingdom

Mohamad E. Allaf, MD

Buerger Family Scholar
Associate Professor of Urology, Oncology,
and Biomedical Engineering
Director of Minimally Invasive and
Robotic Surgery
Department of Urology
James Buchanan Brady Urological Institute
Johns Hopkins University School of
Medicine
Baltimore, Maryland

Karl-Erik Andersson, MD, PhD

Professor
Aarhus Institute for Advanced Studies
Aarhus University
Aarhus, Jutland, Denmark;
Professor
Wake Forest Institute for Regenerative
Medicine
Wake Forest University School of Medicine
Winston-Salem, North Carolina

**Sero Andonian, MD, MSc, FRCS(C),
FACS**

Associate Professor
Division of Urology
Department of Surgery
McGill University
Montreal, Quebec, Canada

Jennifer Tash Anger, MD, MPH

Associate Professor
Department of Surgery
Cedars-Sinai Medical Center;
Adjunct Assistant Professor
Urology
University of California, Los Angeles
Los Angeles, California

Kenneth W. Angermeier, MD

Associate Professor
Clickman Urological and Kidney Institute
Cleveland Clinic
Cleveland, Ohio

Emmanuel S. Antonarakis, MD

Associate Professor of Oncology
Sidney Kimmel Comprehensive Cancer
Center
Johns Hopkins University
Baltimore, Maryland

Jodi A. Antonelli, MD

Assistant Professor
Department of Urology
University of Texas Southwestern Medical
Center
Dallas, Texas

Anthony Atala, MD

Director, Wake Forest Institute for
Regenerative Medicine
William H. Boyce Professor and Chair
Department of Urology
Wake Forest School of Medicine
Winston-Salem, North Carolina

Paul F. Austin, MD

Professor
Division of Urologic Surgery
Washington University School of Medicine
in St. Louis
St. Louis, Missouri

Gopal H. Badlani, MD, FACS

Professor and Vice Chair
Department of Urology
Wake Forest University Baptist Medical
Center
Winston-Salem, North Carolina

**Darius J. Bägli, MDCM, FRCSC, FAAP,
FACS**

Professor of Surgery and Physiology
Division of Urology, Departments of
Surgery and Physiology
University of Toronto;
Senior Attending Urologist, Associate
Surgeon-in-Chief, Senior Associate
Scientist
Division of Urology, Department of
Surgery, Division of Developmental and
Stem Cell Biology
Sick Kids Hospital and Research Institute
Toronto, Ontario, Canada

Daniel A. Barocas, MD, MPH, FACS

Assistant Professor
Department of Urologic Surgery
Vanderbilt University Medical Center
Nashville, Tennessee

Julia Spencer Barthold, MD

Associate Chief
Surgery/Urology
Nemours/Alfred I. duPont Hospital for
Children
Wilmington, Delaware;
Professor
Departments of Urology and Pediatrics
Sidney Kimmel Medical College of
Thomas Jefferson University
Philadelphia, Pennsylvania

Stuart B. Bauer, MD

Professor of Surgery (Urology)
Harvard Medical School;
Senior Associate in Urology
Department of Urology
Boston Children's Hospital
Boston, Massachusetts

Mitchell C. Benson, MD

Department of Urology
New York-Presbyterian Hospital/Columbia
University Medical Center
New York, New York;

Brian M. Benway, MD

Director, Comprehensive Kidney Stone
Program
Urology Academic Practice
Cedars-Sinai Medical Center
Los Angeles, California

Jonathan Bergman, MD, MPH

Assistant Professor
Departments of Urology and Family
Medicine
David Geffen School of Medicine at UCLA;
Veterans Health Affairs, Greater Los
Angeles
Los Angeles, California

Sara L. Best, MD

Assistant Professor
Department of Urology
University of Wisconsin School of
Medicine and Public Health
Madison, Wisconsin

Sam B. Bhayani, MD, MS

Professor of Surgery, Urology
Department of Surgery
Washington University School of Medicine
in St. Louis;
Vice President, Chief Medical Officer
Barnes West Hospital
St. Louis, Missouri

Lori A. Birder, PhD

Professor of Medicine and Pharmacology
Medicine-Renal Electrolyte Division
University of Pittsburgh School of
Medicine
Pittsburgh, Pennsylvania

Jay T. Bishoff, MD, FACS

Director, Intermountain Urological
Institute
Intermountain Health Care
Salt Lake City, Utah

Brian G. Blackburn, MD

Clinical Associate Professor
Department of Internal Medicine/
Infectious Diseases and Geographic
Medicine
Stanford University School of Medicine
Stanford, California

Jeremy Matthew Blumberg, MD

Chief of Urology
Harbor-UCLA Medical Center;
Assistant Professor of Urology
David Geffen School of Medicine at UCLA
Los Angeles, California

Michael L. Blute, Sr., MD

Chief, Department of Urology
Walter S. Kerr, Jr., Professor of Urology
Massachusetts General Hospital/Harvard
Medical School
Boston, Massachusetts

Timothy B. Boone, MD, PhD

Professor and Chair
Department of Urology
Houston Methodist Hospital and Research
Institute
Houston, Texas;
Professor
Department of Urology
Weill Medical College of Cornell
University
New York, New York

Stephen A. Boorjian, MD

Professor of Urology
Department of Urology
Mayo Clinic
Rochester, Minnesota

Joseph G. Borer, MD

Associate Professor of Surgery (Urology)
Harvard Medical School;
Reconstructive Urologic Surgery Chair
Director, Neurourology and Urodynamics
Director, Bladder Exstrophy Program
Department of Urology
Boston Children's Hospital
Boston, Massachusetts

Charles B. Brendler, MD

Co-Director, John and Carol Walter Center
for Urological Health
Department of Surgery
Division of Urology
NorthShore University HealthSystem
Evanston, Illinois;
Senior Clinician Educator
Department of Surgery
Division of Urology
University of Chicago Pritzker School of
Medicine
Chicago, Illinois

Gregory A. Broderick, MD

Professor of Urology
Mayo Clinic College of Medicine
Program Director, Urology Residency
Program
Mayo Clinic
Jacksonville, Florida

James D. Brooks, MD

Keith and Jan Hurlbut Professor
Chief of Urologic Oncology
Department of Urology
Stanford University
Stanford, California

Benjamin M. Brucker, MD

Assistant Professor
Urology and Obstetrics & Gynecology
NYU Langone Medical Center
New York, New York

Kathryn L. Burgio, PhD

Professor of Medicine
Department of Medicine
Division of Gerontology, Geriatrics, and
Palliative Care
University of Alabama at Birmingham;
Associate Director for Research
Birmingham/Atlanta Geriatric Research,
Education, and Clinical Center
Birmingham VA Medical Center
Birmingham, Alabama

Arthur L. Burnett II, MD, MBA, FACS

Patrick C. Walsh Distinguished Professor
of Urology
Department of Urology
Johns Hopkins University School of
Medicine
Baltimore, Maryland

Nicol Corbin Bush, MD, MSCS

Co-Director, PARC Urology
Dallas, Texas

Jeffrey A. Cadeddu, MD

Professor of Urology and Radiology
Department of Urology
University of Texas Southwestern Medical
Center
Dallas, Texas

Anthony A. Caldamone, MD, MMS, FAAP, FACS

Professor of Surgery (Urology)
Division of Urology
Section of Pediatric Urology
Warren Alpert Medical School of Brown
University;
Chief of Pediatric Urology
Division of Pediatric Urology
Hasbro Children's Hospital
Providence, Rhode Island

Steven C. Campbell, MD, PhD

Professor of Surgery
Department of Urology
Glickman Urological and Kidney Institute
Cleveland Clinic
Cleveland, Ohio

Douglas A. Canning, MD

Professor of Urology (Surgery)
Perelman School of Medicine
University of Pennsylvania;
Chief, Division of Urology
The Children's Hospital of Philadelphia
Philadelphia, Pennsylvania

Michael A. Carducci, MD

AEGON Professor in Prostate Cancer
Research
Sidney Kimmel Comprehensive Cancer
Center
Johns Hopkins University
Baltimore, Maryland

Peter R. Carroll, MD, MPH

Professor and Chair
Ken and Donna Derr-Chevron
Distinguished Professor
Department of Urology
University of California, San Francisco
San Francisco, California

Herbert Ballentine Carter, MD

Professor of Urology and Oncology
Department of Urology
James Buchanan Brady Urological Institute
Johns Hopkins School of Medicine
Baltimore, Maryland

Clint K. Cary, MD, MPH

Assistant Professor
Department of Urology
Indiana University
Indianapolis, Indiana

Pasquale Casale, MD

Professor
Department of Urology
Columbia University Medical Center;
Chief, Pediatric Urology
Morgan Stanley Children's Hospital of
New York-Presbyterian
New York, New York

William J. Catalona, MD

Professor
Department of Urology
Northwestern University Feinberg School
of Medicine
Chicago, Illinois

Frank A. Celigoj, MD

Male Infertility/Andrology Fellow
Department of Urology
University of Virginia
Charlottesville, Virginia

Toby C. Chai, MD

Vice Chair of Research
Department of Urology
Yale School of Medicine;
Co-Director of Female Pelvic Medicine and
Reconstructive Surgery Program
Department of Urology
Yale New Haven Hospital
New Haven, Connecticut

Alicia H. Chang, MD, MS

Instructor
Department of Internal Medicine/
Infectious Diseases and Geographic
Medicine
Stanford University School of Medicine
Stanford, California;
Medical Consultant
Los Angeles County Tuberculosis Control
Program
Los Angeles County Department of Public
Health
Los Angeles, California

Christopher R. Chapple, MD, FRCS (Urol)

Professor and Consultant Urologist
Department of Urology
The Royal Hallamshire Hospital
Sheffield Teaching Hospitals
Sheffield, South Yorkshire, United
Kingdom

Mang L. Chen, MD

Assistant Professor
Department of Urology
University of Pittsburgh
Pittsburgh, Pennsylvania

Ronald C. Chen, MD, MPH

Associate Professor
Department of Radiation Oncology
University of North Carolina at Chapel
Hill
Chapel Hill, North Carolina

Benjamin I. Chung, MD

Assistant Professor
Department of Urology
Stanford University School of Medicine
Stanford, California

Michael J. Conlin, MD, MCR

Associate Professor of Urology
Portland VA Medical Center
Portland, Oregon

Christopher S. Cooper, MD, FAAP, FACS

Professor
Department of Urology
University of Iowa;
Associate Dean, Student Affairs and
Curriculum
University of Iowa Carver College of
Medicine
Iowa City, Iowa

Raymond A. Costabile, MD

Jay Y. Gillenwater Professor of Urology
Department of Urology
University of Virginia
Charlottesville, Virginia

Paul L. Crispen, MD

Assistant Professor
Department of Urology
University of Florida
Gainesville, Florida

Juanita M. Crook, MD, FRCPC

Professor
Division of Radiation Oncology
University of British Columbia, Okanagan;
Radiation Oncologist
Center for the Southern Interior
British Columbia Cancer Agency
Kelowna, British Columbia, Canada

Douglas M. Dahl, MD, FACS

Associate Professor of Surgery
Harvard Medical School;
Chief, Division of Urologic Oncology
Department of Urology
Massachusetts General Hospital
Boston, Massachusetts

Marc Arnaldo Dall'Era, MD

Associate Professor
Department of Urology
University of California, Davis
Sacramento, California

Anthony V. D'Amico, MD, PhD

Eleanor Theresa Walters Distinguished
Professor and Chief of Genitourinary
Radiation Oncology
Department of Radiation Oncology
Brigham and Women's Hospital and
Dana-Farber Cancer Institute
Boston, Massachusetts

Siamak Daneshmand, MD

Professor of Urology (Clinical Scholar)
Institute of Urology
University of Southern California
Los Angeles, California

Shubha De, MD, FRCPC

Assistant Professor
University of Alberta
Edmonton, Alberta, Canada

Jean J. M. C. H. de la Rosette, MD, PhD

Professor and Chairman
Department of Urology
AMC University Hospital
Amsterdam, Netherlands

Dirk J. M. K. De Ridder, MD, PhD

Professor
Department of Urology
University Hospitals KU Leuven
Leuven, Belgium

G. Joel DeCastro, MD, MPH

Assistant Professor of Urology
Department of Urology
New York-Presbyterian Hospital/Columbia
University Medical Center
New York, New York

Michael C. Degen, MD, MA

Clinical Assistant
Department of Urology
Hackensack University Medical Center
Hackensack, New Jersey

Sevag Demirjian, MD

Assistant Professor
Cleveland Clinic Lerner College of
Medicine
Department of Nephrology and
Hypertension
Cleveland Clinic
Cleveland, Ohio

Francisco Tibor Dénes, MD, PhD

Associate Professor
Division of Urology
Chief, Pediatric Urology
University of São Paulo Medical School
Hospital das Clínicas
São Paulo, Brazil

John D. Denstedt, MD, FRCSC, FACS

Professor of Urology
Chairman of the Department of Surgery
Western University
London, Ontario, Canada

Reproductive Urologist
Austin Fertility & Reproductive Medicine;
Adjunct Assistant Professor
Neuroendocrinology and Motivation
Laboratory
Department of Psychology
The University of Texas at Austin
Austin, Texas

Antoine E. Khoury, MD, FRCSC, FAAP
Walter R. Schmid Professor of Urology
University of California, Irvine;
Head of Pediatric Urology
CHOC Children's Urology Center
Children's Hospital of Orange County
Orange, California

Roger S. Kirby, MD, FRCS
Medical Director
The Prostate Center
London, United Kingdom

Eric A. Klein, MD
Chairman
Glickman Urological and Kidney Institute
Cleveland Clinic;
Professor of Surgery
Cleveland Clinic Lerner College of
Medicine
Cleveland, Ohio

David James Klumpp, PhD
Associate Professor
Department of Urology
Northwestern University Feinberg School
of Medicine
Chicago, Illinois

Bodo E. Knudsen, MD, FRCSC
Associate Professor and Interim Chair,
Clinical Operations
Department of Urology
Wexner Medical Center
The Ohio State University
Columbus, Ohio

Kathleen C. Kobashi, MD, FACS
Section Head
Urology and Renal Transplantation
Virginia Mason Medical Center
Seattle, Washington

Thomas F. Kolon, MD, MS
Associate Professor of Urology (Surgery)
Perelman School of Medicine
University of Pennsylvania;
Director, Pediatric Urology Fellowship
Program
The Children's Hospital of Philadelphia
Philadelphia, Pennsylvania

Bridget F. Koontz, MD
Butler-Harris Assistant Professor
Department of Radiation Oncology
Duke University Medical Center
Durham, North Carolina

**Martin Allan Koyle, MD, FAAP, FACS,
FRCS, FRCS (Eng)**
Division Head, Pediatric Urology
Women's Auxiliary Chair in Urology and
Regenerative Medicine
Hospital for Sick Children;
Professor
Department of Surgery
Division of Urology
Institute of Health Policy, Management
and Evaluation
University of Toronto
Toronto, Ontario, Canada

Amy E. Krambeck, MD
Associate Professor
Department of Urology
Mayo Clinic
Rochester, Minnesota

Ryan M. Krlin, MD
Assistant Professor of Urology
Department of Urology
Louisiana State University Health Science
Center
New Orleans, Louisiana

Bradley P. Kropp, MD, FAAP, FACS
Professor of Pediatric Urology
Department of Urology
University of Oklahoma Health Sciences
Center
Oklahoma City, Oklahoma

Alexander Kutikov, MD, FACS
Associate Professor of Urologic Oncology
Department of Surgery
Fox Chase Cancer Center
Philadelphia, Pennsylvania

Jaime Landman, MD
Professor of Urology and Radiology
Chairman, Department of Urology
University of California, Irvine
Orange, California

Brian R. Lane, MD, PhD
Betz Family Endowed Chair for Cancer
Research
Spectrum Health Regional Cancer Center;
Chief of Urology
Spectrum Health Medical Group;
Associate Professor of Surgery
Michigan State University;
Grand Rapids, Michigan

Stephen Larsen, MD
Chief Resident
Department of Urology
Rush University Medical Center
Chicago, Illinois

David A. Leavitt, MD
Assistant Professor
Vattikuti Urology Institute
Henry Ford Health System
Detroit, Michigan

Eugene Kang Lee, MD
Assistant Professor
Department of Urology
University of Kansas Medical Center
Kansas City, Kansas

Richard S. Lee, MD
Assistant Professor of Surgery (Urology)
Harvard Medical School;
Department of Urology
Boston Children's Hospital
Boston, Massachusetts

W. Robert Lee, MD, MEd, MS
Professor
Department of Radiation Oncology
Duke University School of Medicine
Durham, North Carolina

Dan Leibovici, MD
Chairman of Urology
Kaplan Hospital
Rehovot, Israel

Gary E. Lemack, MD
Professor of Urology and Neurology
Department of Urology
University of Texas Southwestern Medical
Center
Dallas, Texas

Herbert Lepor, MD
Professor and Martin Spatz Chairman
Department of Urology
NYU Langone Medical Center
New York, New York

Laurence A. Levine, MD, FACS
Professor
Department of Urology
Rush University Medical Center
Chicago, Illinois

**Sey Kiat Lim, MBBS, MRCS (Edinburgh),
MMed (Surgery), FAMS (Urology)**
Consultant
Department of Urology
Changi General Hospital
Singapore

W. Marston Linehan, MD
Chief, Urologic Oncology Branch
Physician-in-Chief, Urologic Surgery
National Cancer Institute
National Institutes of Health Clinical
Center
Bethesda, Maryland

James E. Lingeman, MD
Professor
Department of Urology
Indiana University School of Medicine
Indianapolis, Indiana

Richard Edward Link, MD, PhD
Associate Professor of Urology
Director, Division of Endourology and
Minimally Invasive Surgery
Scott Department of Urology
Baylor College of Medicine
Houston, Texas

Michael E. Lipkin, MD
Associate Professor
Division of Urologic Surgery
Duke University Medical Center
Durham, North Carolina

Mark S. Litwin, MD, MPH
The Fran and Ray Stark Foundation Chair
in Urology
Professor of Urology and Health Policy &
Management
David Geffen School of Medicine at UCLA
UCLA Fielding School of Public Health
Los Angeles, California

Stacy Loeb, MD, MSc
Assistant Professor
Urology, Population Health, and Laura
and Isaac Perlmutter Cancer Center
New York University and Manhattan
Veterans Affairs
New York, New York

**Armando J. Lorenzo, MD, MSc, FRCSC,
FAAP, FACS**
Staff Paediatric Urologist
Hospital for Sick Children
Associate Scientist
Research Institute, Child Health Evaluative
Sciences;
Associate Professor
Department of Surgery
Division of Urology
University of Toronto
Toronto, Ontario, Canada

Yair Lotan, MD
Professor
Department of Urology
University of Texas Southwestern Medical
Center
Dallas, Texas

Tom F. Lue, MD, ScD (Hon), FACS
Professor
Department of Urology
University of California, San Francisco
San Francisco, California

Dawn Lee MacLellan, MD, FRCSC
Associate Professor
Departments of Urology and Pathology
Dalhousie University
Halifax, Nova Scotia, Canada

Vitaly Margulis, MD
Associate Professor
Department of Urology
University of Texas Southwestern Medical
Center
Dallas, Texas

Stephen David Marshall, MD
Chief Resident
Department of Urology
SUNY Downstate College of Medicine
Brooklyn, New York

Aaron D. Martin, MD, MPH
Assistant Professor
Department of Urology
Louisiana State University Health Sciences
Center;
Pediatric Urology
Children's Hospital New Orleans
New Orleans, Louisiana

Darryl T. Martin, PhD
Associate Research Scientist
Department of Urology
Yale University School of Medicine
New Haven, Connecticut

Neil Martin, MD, MPH
Assistant Professor
Department of Radiation Oncology
Brigham and Women's Hospital and
Dana-Farber Cancer Institute
Boston, Massachusetts

Timothy A. Masterson, MD
Associate Professor
Department of Urology
Indiana University Medical Center
Indianapolis, Indiana

Ranjiv Mathews, MD
Professor of Urology and Pediatrics
Director of Pediatric Urology
Southern Illinois University School of
Medicine
Springfield, Illinois

Surena F. Matin, MD
Professor
Department of Urology;
Medical Director
Minimally Invasive New Technology in
Oncologic Surgery (MINTOS)
The University of Texas MD Anderson
Cancer Center
Houston, Texas

Brian R. Matlaga, MD, MPH
Professor
James Buchanan Brady Urological Institute
Johns Hopkins Medical Institutions
Baltimore, Maryland

Richard S. Matulewicz, MS, MD
Department of Urology
Northwestern University Feinberg School
of Medicine
Chicago, Illinois

Kurt A. McCammon, MD, FACS
Devine Chair in Genitourinary
Reconstructive Surgery
Chairman and Program Director
Professor
Department of Urology
Eastern Virginia Medical School;
Sentara Norfolk General Hospital
Urology
Norfolk, Virginia;
Devine-Jordan Center for Reconstructive
Surgery and Pelvic Health
Urology of Virginia, PLLC
Virginia Beach, Virginia

James M. McKiernan, MD
Chairman
Department of Urology
New York-Presbyterian Hospital/Columbia
University Medical Center
New York, New York

Alan W. McMahon, MD
Associate Professor
Department of Medicine
University of Alberta
Edmonton, Alberta, Canada

Chris G. McMahon, MBBS, FACHSHM
Director, Australian Centre for Sexual
Health
Sydney, New South Wales, Australia

**Thomas A. McNicholas, MB, BS, FRCS,
FEBU**
Consultant Urologist and Visiting
Professor
Department of Urology
Lister Hospital and University of
Hertfordshire
Stevenage, United Kingdom

Kevin T. McVary, MD, FACS
Professor and Chairman, Division of
Urology
Department of Surgery
Southern Illinois University School of
Medicine
Springfield, Illinois

Alan K. Meeker, PhD
Assistant Professor of Pathology
Assistant Professor of Urology
Assistant Professor of Oncology
Johns Hopkins University School of
Medicine
Baltimore, Maryland

Kirstan K. Meldrum, MD
Chief, Division of Pediatric Urology
Professor of Surgery
Michigan State University
Helen DeVos Children's Hospital
Grand Rapids, Michigan

Cathy Mendelsohn, PhD

Professor
Departments of Urology, Pathology, and
Genetics & Development
Columbia University College of Physicians
and Surgeons
New York, New York

Maxwell V. Meng, MD

Professor
Chief, Urologic Oncology
Department of Urology
University of California, San Francisco
San Francisco, California

Jayadev Reddy Mettu, MD, MBBS

Department of Urology
Wake Forest School of Medicine
Winston-Salem, North Carolina

Alireza Moinzadeh, MD

Director of Robotic Surgery
Institute of Urology
Lahey Hospital & Medical Center
Burlington, Massachusetts;
Assistant Professor
Department of Urology
Tufts University School of Medicine
Boston, Massachusetts

Manoj Monga, MD, FACS

Director, Stevan B. Strem Center for
Endourology and Stone Disease
Glickman Urological and Kidney Institute
Cleveland Clinic
Cleveland, Ohio

Allen F. Morey, MD, FACS

Professor
Department of Urology
University of Texas Southwestern Medical
Center
Dallas, Texas

Todd M. Morgan, MD

Assistant Professor
Department of Urology
University of Michigan
Ann Arbor, Michigan

Ravi Munver, MD, FACS

Vice Chairman
Chief of Minimally Invasive and Robotic
Urologic Surgery
Department of Urology
Hackensack University Medical Center
Hackensack, New Jersey;
Associate Professor of Surgery (Urology)
Department of Surgery
Division of Urology
Rutgers New Jersey Medical School
Newark, New Jersey

Stephen Y. Nakada, MD, FACS

Professor and Chairman
The David T. Uehling Chair of Urology
Department of Urology
University of Wisconsin School of
Medicine and Public Health;
Chief of Service
Department of Urology
University of Wisconsin Hospital and
Clinics
Madison, Wisconsin

Leah Yukie Nakamura, MD

Associate in Urology
Orange County Urology Associates
Laguna Hills, California

Neema Navai, MD

Assistant Professor
Department of Urology
The University of Texas MD Anderson
Cancer Center
Houston, Texas

Joel B. Nelson, MD

Frederic N. Schwentker Professor and
Chairman
Department of Urology
University of Pittsburgh School of
Medicine
Pittsburgh, Pennsylvania

Diane K. Newman, DNP, ANP-BC, FAAN

Adjunct Associate Professor of Urology in
Surgery
Division of Urology
Research Investigator Senior
Perelman School of Medicine
University of Pennsylvania;
Co-Director, Penn Center for Continence
and Pelvic Health
Division of Urology
Penn Medicine
Philadelphia, Pennsylvania

Paul L. Nguyen, MD

Associate Professor
Department of Radiation Oncology
Harvard Medical School;
Director of Prostate Brachytherapy
Department of Radiation Oncology
Brigham and Women's Hospital and
Dana-Farber Cancer Institute
Boston, Massachusetts

J. Curtis Nickel, MD, FRCSC

Professor and Canada Research Chair
Department of Urology
Queen's University
Kingston, Ontario, Canada

Craig Stuart Niederberger, MD, FACS

Clarence C. Saelhof Professor and Head
Department of Urology
University of Illinois at Chicago College of
Medicine
Professor of Bioengineering
University of Illinois at Chicago College of
Engineering
Chicago, Illinois

Victor W. Nitti, MD

Professor
Urology and Obstetrics & Gynecology
NYU Langone Medical Center
New York, New York

Victoria F. Norwood, MD

Robert J. Roberts Professor of Pediatrics
Chief of Pediatric Nephrology
Department of Pediatrics
University of Virginia
Charlottesville, Virginia

L. Henning Olsen, MD, DMSc, FEAPU, FEBU

Professor
Department of Urology & Institute of
Clinical Medicine
Section of Pediatric Urology
Aarhus University Hospital & Aarhus
University
Aarhus, Denmark

Aria F. Olumi, MD

Associate Professor of Surgery/Urology
Department of Urology
Massachusetts General Hospital/Harvard
Medical School
Boston, Massachusetts

Michael Ordon, MD, MSc, FRCSC

Assistant Professor
Division of Urology
University of Toronto
Toronto, Ontario, Canada

David James Osborn, MD

Assistant Professor
Division of Urology
Walter Reed National Military Medical
Center
Uniformed Services University
Bethesda, Maryland

Nadir I. Osman, PhD, MRCS

Department of Urology
The Royal Hallmashire Hospital Sheffield
Teaching Hospitals
Sheffield, South Yorkshire, United
Kingdom

Michael C. Ost, MD

Associate Professor and Vice Chairman
Department of Urology
University of Pittsburgh Medical Center;
Chief, Division of Pediatric Urology
Children's Hospital of Pittsburgh at the
University of Pittsburgh Medical Center
Pittsburgh, Pennsylvania

Lance C. Pagliaro, MD

Professor
Department of Genitourinary Medical
Oncology
The University of Texas MD Anderson
Cancer Center
Houston, Texas

Ganesh S. Palapattu, MD
Chief of Urologic Oncology
Associate Professor
Department of Urology
University of Michigan
Ann Arbor, Michigan

Drew A. Palmer, MD
Institute of Urology
Lahey Hospital & Medical Center
Burlington, Massachusetts;
Clinical Associate
Tufts University School of Medicine
Boston, Massachusetts

Jeffrey S. Palmer, MD, FACS, FAAP
Director
Pediatric and Adolescent Urology Institute
Cleveland, Ohio

Lane S. Palmer, MD, FACS, FAAP
Professor and Chief
Pediatric Urology
Cohen Children's Medical Center of New
York/Hofstra North Shore-LIJ School of
Medicine
Long Island, New York

John M. Park, MD

Assistant Professor
Department of Urology
New York University
New York, New York

Jack M. Zuckerman, MD

Fellow in Reconstructive Surgery
Department of Urology
Eastern Virginia Medical School
Norfolk, Virginia

PREFACE

Since it was first published in 1954, Campbell-Walsh Urology (born Urology) has been the gold standard for a comprehensive review of our specialty. We are proud and pleased to present the 11th edition of this text as a worthy successor to the 10 editions that have preceded it. The four volumes remain essentially a series of comprehensive mini-textbooks on every major subject in urology. There are significant changes for this edition in organization, content, and authorship, and these reflect the ever-changing nature of our field, and, for many subjects, the passing of the baton from one generation to the next. Twenty-two totally new chapters have been added, along with 61 new first authors. All other chapters have been revised, new and revised guidelines incorporated, and the well-accepted format of the use of extensive boldface and Key Points boxes and algorithms retained. Ownership of the 11th edition includes the print product, access to the full text online, and a downloadable eBook version through ExpertConsult.com. The online and eBook version of the 11th edition will have updates by key opinion leaders added periodically to reflect important changes and controversies in the field.

Content changes include restructuring of the chapter on basic principles of radiologic imaging in adult urology, a new chapter on pediatric urologic imaging, and separate new chapters on the surgical, radiographic, and endoscopic anatomy of the male reproductive system, the retroperitoneum, the kidney and ureter, the adrenals, and the male and female pelvis. The chapter on androgen deficiency has been expanded to encompass integrated men's health, including cardiovascular risks and metabolic syndrome. There are totally new added chapters on basic energy modalities in urologic surgery, management of urinary tract hemorrhage, strategies for medical management of upper urinary tract calculi, inguinal lymph node dissection, overview of the evaluation and management of urinary incontinence in men, the underactive detrusor, complications related to the use of mesh in the treatment of urinary incontinence and prolapse and their repair, and minimally invasive urinary diversion. Additionally, in the pediatric volume, totally new chapters have been added on the principles of laparoscopic and robotic surgery, functional disorders of the lower urinary tract, management of defecation disorders, and adolescent and transitional urology. Totally new content has been provided for existing chapters on sexually transmitted infections, tuberculosis and other opportunistic infections, the basics of male infertility, disorders of male orgasm and ejaculation, surgery for erectile dysfunction, Peyronie disease, female sexual function and dysfunction, renovascular hypertension and ischemic neuropathy, renal trans-

plantation, and nonmedical management of upper urinary tract calculi. Within the section on urine transport, storage, and emptying, totally new content has been provided for the chapters on physiology and pharmacology of the bladder and urethra, epidemiology and pathophysiology of urinary incontinence and pelvic prolapse, nocturia, conservative management of urinary incontinence, urinary fistulae, geriatric lower urinary tract dysfunction and incontinence, and additional therapies for storage and emptying failure. Reflecting all the latest changes in the field, the chapter on minimally invasive and endoscopic management of benign prostatic hyperplasia has been totally redone. In the area of cancer, many chapters have been totally rewritten to reflect contemporary data and thought: Basic Principles of Immunology and Immunotherapy in Urologic Oncology, Neoplasms of the Testis, Retroperitoneal Tumors, Open Surgery of the Kidney, Nonsurgical Focal Therapy for Renal Tumors, Surgery of the Adrenal Glands, Management of Metastatic and Invasive Bladder Cancer, Transurethral and Open Surgery for Bladder Cancer, Prostate Biopsy: Techniques and Imaging (including fusion techniques), Diagnosis and Staging of Prostate Cancer, Active Surveillance of Prostate Cancer, Focal Therapy for Prostate Cancer, Radiation Therapy for Prostate Cancer, Management of Biochemical Recurrence after Definitive Therapy for Prostate Cancer, and Tumors of the Urethra. In the pediatric volume, a number of existing chapters have been totally rewritten as well: Disorders of Renal Functional Development in Children, Infection and Inflammation of the Pediatric Genitourinary Tract, Surgery of the Ureter in Children, Posterior Urethral Valves, and separate chapters on Management of Abnormalities of the External Genitalia in boys and girls.

We editors are grateful for the support of Elsevier, and special thanks are due to our extraordinary editorial and support staff: Charlotta Kryhl and Stefanie Jewel-Thomas (Senior Content Strategists), Dee Simpson (Senior Content Development Specialist), and Kristine Feeherty (Book Production Specialist). Without their expertise, patience, and gentle pushing, this edition would not have been brought to press on time.

We hope your experience in reading this 11th edition of the gold standard textbook of urology will be as pleasurable as ours has been in watching it develop.

Alan J. Wein, MD, PhD (Hon), FACS

for the editors Louis R. Kavoussi, MD, MBA,
Alan W. Partin, MD, PhD, and Craig A. Peters, MD

CONTENTS

VOLUME 1

PART I Clinical Decision Making

- 1 Evaluation of the Urologic Patient: History, Physical Examination, and Urinalysis, 1**
Glenn S. Gerber, MD, and Charles B. Brendler, MD
- 2 Urinary Tract Imaging: Basic Principles of Computed Tomography, Magnetic Resonance Imaging, and Plain Film, 26**
Jay T. Bishoff, MD, FACS, and Art R. Rastinehad, DO
- 3 Urinary Tract Imaging: Basic Principles of Urologic Ultrasonography, 63**
Bruce R. Gilbert, MD, PhD, and Pat F. Fulgham, MD
- 4 Outcomes Research, 85**
Mark S. Litwin, MD, MPH, and Jonathan Bergman, MD, MPH

PART II Basics of Urologic Surgery

- 5 Core Principles of Perioperative Care, 100**
Manish A. Vira, MD, and Joph Steckel, MD, FACS
- 6 Fundamentals of Urinary Tract Drainage, 119**
Thomas Tailly, MD, MSc, and John D. Denstedt, MD, FRCSC, FACS
- 7 Principles of Urologic Endoscopy, 136**
Brian D. Duty, MD, and Michael J. Conlin, MD, MCR
- 8 Percutaneous Approaches to the Upper Urinary Tract Collecting System, 153**
J. Stuart Wolf, Jr., MD, FACS
- 9 Evaluation and Management of Hematuria, 183**
Stephen A. Boorjian, MD, Jay D. Raman, MD, and Daniel A. Barocas, MD, MPH, FACS
- 10 Fundamentals of Laparoscopic and Robotic Urologic Surgery, 195**
Michael Ordon, MD, MSc, FRCSC, Louis Eichel, MD, and Jaime Landman, MD
- 11 Basic Energy Modalities in Urologic Surgery, 225**
Shubha De, MD, FRCPC, Manoj Monga, MD, FACS, and Bodo E. Knudsen, MD, FRCSC

PART III Infections and Inflammation

- 12 Infections of the Urinary Tract, 237**
Anthony J. Schaeffer, MD, Richard S. Matulewicz, MS, MD, and David James Klumpp, PhD
- 13 Inflammatory and Pain Conditions of the Male Genitourinary Tract: Prostatitis and Related Pain Conditions, Orchitis, and Epididymitis, 304**
J. Curtis Nickel, MD, FRCSC
- 14 Bladder Pain Syndrome (Interstitial Cystitis) and Related Disorders, 334**
Philip M. Hanno, MD, MPH

15 Sexually Transmitted Diseases, 371

Michel Arthur Pontari, MD

16 Cutaneous Diseases of the External Genitalia, 387

Richard Edward Link, MD, PhD, and Theodore Rosen, MD

17 Tuberculosis and Parasitic Infections of the Genitourinary Tract, 421

Alicia H. Chang, MD, MS, Brian G. Blackburn, MD, and Michael H. Hsieh, MD, PhD

PART IV Molecular and Cellular Biology

18 Basic Principles of Immunology and Immunotherapy in Urologic Oncology, 447

Charles G. Drake, MD, PhD

19 Molecular Genetics and Cancer Biology, 459

Mark L. Gonzalgo, MD, PhD, Karen S. Sfanos, PhD, and Alan K. Meeker, PhD

20 Principles of Tissue Engineering, 482

Anthony Atala, MD

PART V Reproductive and Sexual Function

21 Surgical, Radiographic, and Endoscopic Anatomy of the Male Reproductive System, 498

Parviz K. Kavoussi, MD, FACS

22 Male Reproductive Physiology, 516

Paul J. Turek, MD, FACS, FRSM

23 Integrated Men's Health: Androgen Deficiency, Cardiovascular Risk, and Metabolic Syndrome, 538

J. Kellogg Parsons, MD, MHS, FACS, and Tung-Chin Hsieh, MD

24 Male Infertility, 556

Craig Stuart Niederberger, MD, FACS

25 Surgical Management of Male Infertility, 580

Marc Goldstein, MD, DSc (Hon), FACS

26 Physiology of Penile Erection and Pathophysiology of Erectile Dysfunction, 612

Tom F. Lue, MD, ScD (Hon), FACS

27 Evaluation and Management of Erectile Dysfunction, 643

Arthur L. Burnett II, MD, MBA, FACS

28 Priapism, 669

Gregory A. Broderick, MD

29 Disorders of Male Orgasm and Ejaculation, 692

Chris G. McMahon, MBBS, FACHSHM

30 Surgery for Erectile Dysfunction, 709

J. Francois Eid, MD

31 Diagnosis and Management of Peyronie Disease, 722

Laurence A. Levine, MD, FACS, and Stephen Larsen, MD

Evaluation of the Urologic Patient: History, Physical Examination, and Urinalysis

Glenn S. Gerber, MD, and Charles B. Brendler, MD

History

Physical Examination

Urinalysis

Summary

Urologists have a unique position in medicine because their patients encompass all age groups, including prenatal, pediatric, adolescent, adult, and geriatric. Because there is no medical subspecialist with similar interests, **the urologist has the ability to make the initial evaluation and diagnosis and to provide medical and surgical therapy for all diseases of the genitourinary (GU) system.** Historically, the diagnostic armamentarium included urinalysis, endoscopy, and intravenous (IV) pyelography. Recent advances in ultrasonography, computed tomography (CT), magnetic resonance imaging (MRI), and endourology have expanded our diagnostic capabilities. Despite these advances, however, the basic approach to the patient is still dependent on taking a complete history, executing a thorough physical examination, and performing a urinalysis. These basics dictate and guide the subsequent diagnostic evaluation.

HISTORY

Overview

The medical history is the cornerstone of the evaluation of the urologic patient, and a well-taken history will frequently elucidate the probable diagnosis. However, many pitfalls can inhibit the urologist from obtaining an accurate history. The patient may be unable to describe or communicate symptoms because of anxiety, language barrier, or educational background. Therefore the urologist must be a detective and lead the patient through detailed and appropriate questioning to obtain accurate information. There are practical considerations in the art of history-taking that can help to alleviate some of these difficulties. In the initial meeting, an attempt should be made to help the patient feel comfortable. During this time, the physician should project a calm, caring, and competent image that can help foster two-way communication. Impaired hearing, mental capacity, and facility with English can be assessed promptly. These difficulties are frequently overcome by having a family member present during the interview or, alternatively, by having an interpreter present.

Patients need to have sufficient time to express their problems and the reasons for seeking urologic care; the physician, however, should focus the discussion to make it as productive and informative as possible. Direct questioning can then proceed logically. The physician needs to listen carefully without distractions to obtain and interpret the clinical information provided by the patient. **A complete history can be divided into the chief complaint and history of the present illness, the patient's past medical**

history, and a family history. Each segment can provide significant positive and negative findings that will contribute to the overall evaluation and treatment of the patient.

Chief Complaint and Present Illness

Most urologic patients identify their symptoms as arising from the urinary tract and frequently present to the urologist for the initial evaluation. For this reason, the urologist frequently has the opportunity to act as both the primary physician and the specialist. The chief complaint must be clearly defined because it provides the initial information and clues to begin formulating the differential diagnosis. Most importantly, **the chief complaint is a constant reminder to the urologist as to why the patient initially sought care.** This issue must be addressed even if subsequent evaluation reveals a more serious or significant condition that requires more urgent attention. In our personal experience, a young woman presented with a chief complaint of recurrent urinary tract infections (UTIs). In the course of her evaluation, she was found to have a right adrenal mass. We subsequently focused on this problem and performed a right adrenalectomy for a benign cortical adenoma. We forgot about the woman's original symptoms until she presented for her subsequent postoperative examination. She reminded us of her original symptoms at that time, and subsequent evaluation revealed that she had a nylon suture that had eroded into the anterior wall of her bladder from a previous abdominal vesicourethropepy performed 2 years earlier for stress urinary incontinence. Her UTIs resolved after surgical removal of the suture.

In obtaining the history of the present illness, **the duration, severity, chronicity, periodicity, and degree of disability are important considerations.** The patient's symptoms need to be clarified for details and quantified for severity. Listed next are a variety of typical initial complaints. Specific questions that focus on the differential diagnosis are provided.

Pain

Pain arising from the GU tract may be quite severe and is usually associated with either urinary tract obstruction or inflammation. Urinary calculi cause severe pain when they obstruct the upper urinary tract. Conversely, large, nonobstructing stones may be totally asymptomatic. Thus a 2-mm-diameter stone lodged at the ureterovesical junction may cause excruciating pain, whereas a large staghorn calculus in the renal pelvis or a bladder stone may be totally asymptomatic. Urinary retention from prostatic

obstruction is also quite painful, but the diagnosis is usually obvious to the patient.

Inflammation of the GU tract is most severe when it involves the parenchyma of a GU organ. This is due to edema and distention of the capsule surrounding the organ. Thus pyelonephritis, prostatitis, and epididymitis are typically quite painful. Inflammation of the mucosa of a hollow viscus such as the bladder or urethra usually produces discomfort, but the pain is not nearly as severe.

Tumors in the GU tract usually do not cause pain unless they produce obstruction or extend beyond the primary organ to involve adjacent nerves. Thus pain associated with GU malignancies is usually a late manifestation and a sign of advanced disease.

Renal Pain. Pain of renal origin is usually located in the ipsilateral costovertebral angle just lateral to the sacrospinalis muscle and beneath the 12th rib. Pain is usually caused by acute distention of the renal capsule, generally from inflammation or obstruction. The pain may radiate across the flank anteriorly toward the upper abdomen and umbilicus and may be referred to the testis or labium. A corollary to this observation is that renal or retroperitoneal disease should be considered in the differential diagnosis of any man who complains of testicular discomfort but has a normal scrotal examination. Pain due to inflammation is usually steady, whereas pain due to obstruction fluctuates in intensity. Thus the pain produced by ureteral obstruction is typically colicky in nature and intensifies with ureteral peristalsis, at which time the pressure in the renal pelvis rises as the ureter contracts in an attempt to force urine past the point of obstruction.

Pain of renal origin may be associated with gastrointestinal symptoms because of reflex stimulation of the celiac ganglion and because of the proximity of adjacent organs (liver, pancreas, duodenum, gallbladder, and colon). Thus renal pain may be confused with pain of intraperitoneal origin; it can usually be distinguished, however, by a careful history and physical examination. Pain that is due to a perforated duodenal ulcer or pancreatitis may radiate into the back, but the site of greatest pain and tenderness is in the epigastrium. Pain of intraperitoneal origin is seldom colicky, as with obstructive renal pain. Furthermore, pain of intraperitoneal origin frequently radiates into the shoulder because of irritation of the diaphragm and phrenic nerve; this does not occur with renal pain. Typically, patients with intraperitoneal pathology prefer to lie motionless to minimize pain, whereas patients with renal pain usually are more comfortable moving around and holding the flank.

Renal pain may also be confused with pain resulting from irritation of the costal nerves, most commonly T10-T12. Such pain has a similar distribution from the costovertebral angle across the flank toward the umbilicus. However, the pain is not colicky in nature. Furthermore, the intensity of radicular pain may be altered by changing position; this is not the case with renal pain.

Ureteral Pain. Ureteral pain is usually acute and secondary to obstruction. The pain results from acute distention of the ureter and by hyperperistalsis and spasm of the smooth muscle of the ureter as it attempts to relieve the obstruction, usually produced by a stone or blood clot. The site of ureteral obstruction can often be determined by the location of the referred pain. With obstruction of the midureter, pain on the right side is referred to the right lower quadrant of the abdomen (McBurney point) and thus may simulate appendicitis; pain on the left side is referred over the left lower quadrant and resembles diverticulitis. Also, the pain may be referred to the scrotum in the male or the labium in the female. Lower ureteral obstruction frequently produces symptoms of vesical irritability, including frequency, urgency, and suprapubic discomfort that may radiate along the urethra in men to the tip of the penis. Often, by taking a careful history, the astute clinician can predict the location of the obstruction. Ureteral pathology that arises slowly or produces only mild obstruction rarely causes pain. Therefore ureteral tumors and stones that cause minimal obstruction are seldom painful.

Vesical Pain. Vesical pain is usually produced either by overdistention of the bladder as a result of acute urinary retention or by inflammation. **Constant suprapubic pain that is unrelated to**

urinary retention is seldom of urologic origin. Furthermore, patients with slowly progressive urinary obstruction and bladder distention (e.g., diabetics with a flaccid neurogenic bladder) frequently have no pain at all despite residual urine volumes over 1 L.

Inflammatory conditions of the bladder usually produce intermittent suprapubic discomfort. Thus the pain in conditions such as bacterial cystitis or interstitial cystitis is usually most severe when the bladder is full and is relieved at least partially by voiding. Patients with cystitis sometimes experience sharp, stabbing suprapubic pain at the end of micturition, and this is termed *strangury*. Furthermore, patients with cystitis frequently experience pain referred to the distal urethra that is associated with irritative voiding symptoms such as urinary frequency and dysuria.

Prostatic Pain. Prostatic pain is usually secondary to inflammation with secondary edema and distention of the prostatic capsule. Pain of prostatic origin is poorly localized, and the patient may complain of lower abdominal, inguinal, perineal, lumbosacral, penile, and/or rectal pain. Prostatic pain is frequently associated with irritative urinary symptoms such as frequency and dysuria, and, in severe cases, marked prostatic edema may produce acute urinary retention.

Penile Pain. Pain in the flaccid penis is usually secondary to inflammation in the bladder or urethra, with referred pain that is experienced maximally at the urethral meatus. Alternatively, penile pain may be produced by *paraphimosis*, a condition in which the uncircumcised penile foreskin is trapped behind the glans penis, resulting in venous obstruction and painful engorgement of the glans penis (see later). Pain in the erect penis is usually due to Peyronie disease or priapism (see later).

Testicular Pain. Scrotal pain may be either primary or referred. **Primary pain arises from within the scrotum and is usually secondary to acute epididymitis or torsion of the testis or testicular appendices.** Because of the edema and pain associated with both acute epididymitis and testicular torsion, it is frequently difficult to distinguish these two conditions. Alternatively, scrotal pain may result from inflammation of the scrotal wall itself. This may result from a simple infected hair follicle or sebaceous cyst, but it may also be secondary to Fournier gangrene, a severe, necrotizing infection arising in the scrotum that can rapidly progress and be fatal unless promptly recognized and treated.

Chronic scrotal pain is usually related to noninflammatory conditions such as a hydrocele or a varicocele, and the pain is generally characterized as a dull, heavy sensation that does not radiate. Because the testes arise embryologically in close proximity to the kidneys, pain arising in the kidneys or retroperitoneum may be referred to the testes. Similarly, the dull pain associated with an inguinal hernia may be referred to the scrotum.

Hematuria

Hematuria is the presence of blood in the urine; **greater than three red blood cells (RBCs) per high-power microscopic field (HPF) is significant.** Patients with gross hematuria are usually frightened by the sudden onset of blood in the urine and frequently present to the emergency department for evaluation, fearing that they may be bleeding excessively. Hematuria of any degree should never be ignored and, in adults, should be regarded as a symptom of urologic malignancy until proved otherwise. In evaluating hematuria, several questions should always be asked, and the answers will enable the urologist to target the subsequent diagnostic evaluation efficiently:

Is the hematuria gross or microscopic?

At what time during urination does the hematuria occur (beginning or end of stream or during entire stream)?

Is the hematuria associated with pain?

Is the patient passing clots?

If the patient is passing clots, do the clots have a specific shape?

Gross versus Microscopic Hematuria. The significance of gross versus microscopic hematuria is simply that the chances of

identifying significant pathology increase with the degree of hematuria. Thus patients with gross hematuria usually have identifiable underlying pathology, whereas it is quite common for patients with minimal degrees of microscopic hematuria to have a negative urologic evaluation.

Timing of Hematuria. The timing of hematuria during urination frequently indicates the site of origin. **Initial hematuria usually arises from the urethra;** it occurs least commonly and is usually secondary to inflammation. Total hematuria is most common and indicates that the bleeding is most likely coming from the bladder or upper urinary tracts. Terminal hematuria occurs at the end of micturition and is usually secondary to inflammation in the area of the bladder neck or prostatic urethra. It occurs at the end of micturition as the bladder neck contracts, squeezing out the last amount of urine.

Association with Pain. Hematuria, although frightening, is usually not painful unless it is associated with inflammation or obstruction. Thus patients with cystitis and secondary hematuria may experience painful urinary irritative symptoms, but the pain is usually not worsened with passage of clots. More commonly, **pain in association with hematuria usually results from upper urinary tract hematuria with obstruction of the ureters with clots.** Passage of these clots may be associated with severe, colicky flank pain similar to that produced by a ureteral calculus, and this helps identify the source of the hematuria.

The American Urological Association (AUA) has published guidelines regarding patients with asymptomatic microhematuria (AMH), which is defined as three or more RBCs per HPF in the absence of an obvious benign cause. A determination of AMH should be based on microscopic, not dipstick, examination of the urine. Careful history, physical examination, and laboratory examination should be done to rule out benign causes of AMH, such as infection, medical renal disease, and others. Once these causes are ruled out, urologic evaluation that includes a measurement of renal function is recommended. If factors such as dysmorphic RBCs, proteinuria, casts, or renal insufficiency are present, nephrologic workup should be considered in addition to the urologic evaluation. AMH that occurs in patients who are anticoagulated still warrants urologic evaluation.

The evaluation of patients over 35 years of age with AMH should include cystoscopy, which is optional in younger patients. However, all patients should have cystoscopy if risk factors such as irritative voiding symptoms, tobacco use, or chemical exposures are present. Radiologic evaluation should be performed in the initial evaluation, and the procedure of choice is multiphasic CT urography with and without IV contrast. Magnetic resonance urography, with or without IV contrast, is an acceptable alternative in patients who cannot undergo multiphasic CT scan. In cases where collecting system detail is needed, noncontrast CT, MRI, or renal ultrasonography with retrograde pyelograms is an acceptable alternative if there is a contraindication to the use of IV contrast.

Among the modalities not recommended in the routine evaluation of patients with AMH are urine cytology, urine markers, and blue light cystoscopy. However, cytology may be useful in those patients with persistent AMH following a negative workup or those with other risk factors for carcinoma in situ, such as irritative voiding symptoms, use of tobacco, or chemical exposures. For patients with persistent AMH, yearly urinalysis should be performed. The presence of two consecutive annual negative urinalyses indicates that no further urinalyses are needed for this purpose. For patients with persistent or recurrent AMH, repeat evaluation within 3 to 5 years should be considered.

Presence of Clots. The presence of clots usually indicates a more significant degree of hematuria, and, accordingly, the probability of identifying significant urologic pathology increases.

Shape of Clots. Usually, if the patient is passing clots, they are amorphous and of bladder or prostatic urethral origin. However, **the presence of vermiform (wormlike) clots, particularly if associated with flank pain, identifies the hematuria as coming from the upper urinary tract** with formation of vermiform clots within the ureter.

It cannot be emphasized strongly enough that **hematuria, particularly in the adult, should be regarded as a symptom of malignancy until proved otherwise and demands immediate urologic examination.** In a patient who presents with gross hematuria, cystoscopy should be performed as soon as possible because frequently the source of bleeding can be readily identified. Cystoscopy will determine whether the hematuria is coming from the urethra, bladder, or upper urinary tract. In patients with gross hematuria secondary to an upper tract source, it is easy to see the jet of red urine pulsing from the involved ureteral orifice.

Although inflammatory conditions may result in hematuria, all patients with hematuria, except perhaps young women with acute bacterial hemorrhagic cystitis, should undergo urologic evaluation. Older women and men who present with hematuria and irritative voiding symptoms may have cystitis secondary to infection arising in a necrotic bladder tumor or, more commonly, flat carcinoma in situ of the bladder. **The most common cause of gross hematuria in a patient older than age 50 years is bladder cancer.**

Lower Urinary Tract Symptoms

Irritative Symptoms. *Frequency* is one of the most common urologic symptoms. The normal adult voids five or six times per day, with a volume of approximately 300 mL with each void. **Urinary frequency is due to either increased urinary output (polyuria) or decreased bladder capacity.** If voiding is noted to occur in large amounts frequently, the patient has polyuria and should be evaluated for diabetes mellitus, diabetes insipidus, or excessive fluid ingestion. Causes of decreased bladder capacity include bladder outlet obstruction with decreased compliance, increased residual urine, and/or decreased functional capacity due to irritation, neurogenic bladder with increased sensitivity and decreased compliance, pressure from extrinsic sources, or anxiety. By separating irritative from obstructive symptoms, the astute clinician should be able to arrive at a proper differential diagnosis.

Nocturia is nocturnal frequency. Normally, adults arise no more than twice at night to void. As with frequency, nocturia may be secondary to increased urine output or decreased bladder capacity. **Frequency during the day without nocturia is usually of psychogenic origin and related to anxiety.** Nocturia without frequency may occur in the patient with congestive heart failure and peripheral edema in whom the intravascular volume and urine output increase when the patient is supine. Renal concentrating ability decreases with age; therefore urine production in the geriatric patient is increased at night, when renal blood flow is increased as a result of recumbency. In general, nocturia may be attributed to nocturnal polyuria (nocturnal urine overproduction) and/or diminished nocturnal bladder capacity (Weiss and Blaivas, 2000). Nocturia may also occur in people who drink large amounts of liquid in the evening, particularly caffeinated and alcoholic beverages, which have strong diuretic effects. In the absence of these factors, nocturia signifies a problem with bladder function secondary to urinary outlet obstruction and/or decreased bladder compliance.

Dysuria is painful urination that is usually caused by inflammation. **This pain is usually not felt over the bladder but is commonly referred to the urethral meatus.** Pain occurring at the start of urination may indicate urethral pathology, whereas pain occurring at the end of micturition (strangury) is usually of bladder origin. Dysuria is frequently accompanied by frequency and urgency.

Obstructive Symptoms. *Decreased force of urination* is usually secondary to bladder outlet obstruction and commonly results from benign prostatic hyperplasia (BPH) or a urethral stricture. In fact, except for severe degrees of obstruction, **most patients are unaware of a change in the force and caliber of their urinary stream.** These changes usually occur gradually and go generally unrecognized by most patients. The other obstructive symptoms noted later are more commonly recognized and are usually secondary to bladder outlet obstruction in men due to either BPH or a urethral stricture.

Urinary hesitancy refers to a delay in the start of micturition. Normally, urination begins within a second after relaxing the

urinary sphincter, but it may be delayed in men with bladder outlet obstruction.

Intermittency refers to involuntary start-stopping of the urinary stream. It most commonly results from prostatic obstruction with intermittent occlusion of the urinary stream by the lateral prostatic lobes.

Postvoid dribbling refers to the terminal release of drops of urine at the end of micturition. This is secondary to a small amount of residual urine in either the bulbar or the prostatic urethra that is normally “milked back” into the bladder at the end of micturition (Stephenson and Farrar, 1977). In men with bladder outlet obstruction, this urine escapes into the bulbar urethra and leaks out at the end of micturition. Men will frequently attempt to avoid wetting their clothing by shaking the penis at the end of micturition. In fact, this is ineffective, and the problem is more readily solved by manual compression of the bulbar urethra in the perineum and blotting the urethral meatus with a tissue. Postvoid dribbling is often an early symptom of urethral obstruction related to BPH, but, in itself, seldom necessitates any further treatment.

Straining refers to the use of abdominal musculature to urinate. Normally, it is unnecessary for a man to perform a Valsalva maneuver except at the end of urination. Increased straining during micturition is a symptom of bladder outlet obstruction.

It is important for the urologist to distinguish irritative from obstructive lower urinary tract symptoms. This most frequently occurs in evaluating men with BPH. Although BPH is primarily obstructive, it produces changes in bladder compliance that result in increased irritative symptoms. In fact, men with BPH more commonly present with irritative than obstructive symptoms, and the most common presenting symptom is nocturia. **The urologist must be careful not to attribute irritative symptoms to BPH unless there is documented evidence of obstruction.** In general, lower urinary tract symptoms are nonspecific and may occur secondary to

a wide variety of neurologic conditions, as well as to prostatic enlargement (Lepor and Machi, 1993). In this regard, two important examples are mentioned. Patients with high-grade flat carcinoma in situ of the bladder may present with urinary irritative symptoms. The urologist should be particularly aware of the diagnosis of carcinoma in situ in men who present with irritative symptoms, a history of cigarette smoking, and microscopic hematuria. In our personal experience, we cared for a 54-year-old man who presented with this history and was treated for BPH for 2 years before the diagnosis of bladder cancer was established. Once the correct diagnosis was made, the patient had developed muscle-invasive disease and required a cystectomy for cure.

The second important example is irritative symptoms resulting from neurologic disease such as cerebrovascular accidents, diabetes mellitus, and Parkinson disease. Most neurologic diseases encountered by the urologist are upper motor neuron in etiology and result in a loss of cortical inhibition of voiding with resultant decreased bladder compliance and irritative voiding symptoms. The urologist must be extremely careful to rule out underlying neurologic disease before performing surgery to relieve bladder outlet obstruction. Such surgery not only may fail to relieve the patient's irritative symptoms but also may result in permanent urinary incontinence.

Since its introduction in 1992, the AUA symptom index has been widely used and validated as an important means of assessing men with lower urinary tract symptoms (Barry et al, 1992). The original AUA symptom score is based on the answers to seven questions concerning frequency, nocturia, weak urinary stream, hesitancy, intermittency, incomplete bladder emptying, and urgency. The International Prostate Symptom Score (I-PSS) includes these seven questions, as well as a global quality-of-life question (Table 1-1). The total symptom score ranges from 0 to 35 with scores of 0 to 7, 8 to 19, and 20 to 35 indicating mild, moderate, and severe

TABLE 1-1 International Prostate Symptom Score

SYMPTOM	NOT AT ALL	<1 TIME IN 5	LESS THAN HALF THE TIME	ABOUT HALF THE TIME	MORE THAN HALF THE TIME	ALMOST ALWAYS	YOUR SCORE
1. INCOMPLETE EMPTYING							
Over the past month, how often have you had a sensation of not emptying your bladder completely after you finished urinating?	0	1	2	3	4	5	
2. FREQUENCY							
Over the past month, how often have you had to urinate again less than 2 hours after you finished urinating?	0	1	2	3	4	5	
3. INTERMITTENCY							
Over the past month, how often have you found you stopped and started again several times when you urinated?	0	1	2	3	4	5	
4. URGENCY							
Over the past month, how often have you found it difficult to postpone urination?	0	1	2	3	4	5	

TABLE 1-1 International Prostate Symptom Score—cont'd

SYMPTOM	NOT AT ALL	<1 TIME IN 5	LESS THAN HALF THE TIME	ABOUT HALF THE TIME	MORE THAN HALF THE TIME	ALMOST ALWAYS	YOUR SCORE
5. WEAK STREAM							
Over the past month, how often have you had a weak urinary stream?	0	1	2	3	4	5	
6. STRAINING							
Over the past month, how often have you had to push or strain to begin urination?	0	1	2	3	4	5	
	NONE	1 TIME	2 TIMES	3 TIMES	4 TIMES	≥5 TIMES	
7. NOCTURIA							
Over the past month, how many times did you most typically get up to urinate from the time you went to bed at night until the time you got up in the morning?	0	1	2	3	4	5

QUALITY OF LIFE DUE TO URINARY SYMPTOMS	DELIGHTED	PLEASED	MOSTLY SATISFIED	MIXED—ABOUT EQUALLY SATISFIED AND DISSATISFIED	MOSTLY DISSATISFIED	UNHAPPY	TERRIBLE
If you were to spend the rest of your life with your urinary condition just the way it is now, how would you feel about that?	0	1	2	3	4	5	6

From Cockett A, Aso Y, Denis L. Prostate symptom score and quality of life assessment. In: Cockett ATK, Khoury S, Aso Y, et al, editors. Proceedings of the Second International Consultation on Benign Prostatic Hyperplasia (BPH); 27-30 June 1993; Paris. Channel Island, Jersey: Scientific Communication International; 1994. p. 553-5.

lower urinary tract symptoms, respectively. The I-PSS is a helpful tool both in the clinical management of men with lower urinary tract symptoms and in research studies regarding the medical and surgical treatment of men with voiding dysfunction.

The use of symptom indices has limitations, and it is important for the physician to discuss the patient's responses with him. It has been demonstrated that a grade 6 reading level is necessary to understand the I-PSS, and some patients with neurologic disorders and dementia may also have difficulty completing the symptom score (MacDiarmid et al, 1998). In addition, the symptom score and obstructive and irritative voiding symptoms are nonspecific, and the symptoms may be caused by a variety of conditions other than BPH. Similar symptom scores have been demonstrated to be present in age-matched men and women between 55 and 79 years of age (Lepor and Machi, 1993). Despite these limitations, the I-PSS is a simple adjunct in assessing men with lower urinary tract symptoms and may be used in the initial evaluation of men with lower urinary tract symptoms, as well as in the assessment of treatment response.

Incontinence. Urinary incontinence is the involuntary loss of urine. A careful history of the incontinent patient will often determine the etiology. Urinary incontinence can be subdivided into four categories.

Continuous Incontinence. Continuous incontinence is most commonly due to a urinary tract fistula that bypasses the urethral sphincter. The most common type of fistula that results in urinary incontinence is a vesicovaginal fistula usually secondary to gynecologic surgery, radiation, or obstetric trauma. Less commonly, ureterovaginal fistulae may occur from similar causes.

A second major cause of continuous incontinence is an ectopic ureter that enters either the urethra or the female genital tract. An ectopic ureter usually drains a small, dysplastic upper pole segment of kidney, and the amount of urinary leakage may be quite small. Such patients may void most of their urine normally but have a continuous amount of small urinary leakage that may be misdiagnosed for many years as a chronic vaginal discharge. In our experience, we cared for a 30-year-old woman—who had been misdiagnosed with enuresis in childhood and as having a chronic vaginal discharge in adult life—whose urinary leakage was totally corrected by surgical removal of the dysplastic, upper pole segment of her right kidney. Ectopic ureters never produce urinary incontinence in males because they always enter the bladder neck or prostatic urethra proximal to the external urethral sphincter.

Stress Incontinence. Stress incontinence refers to the sudden leakage of urine with coughing, sneezing, exercise, or other

activities that increase intra-abdominal pressure. During these activities, intra-abdominal pressure rises transiently above urethral resistance, resulting in a sudden, usually small amount of urinary leakage. Stress incontinence is most common in women after childbearing or menopause and is related to a loss of anterior vaginal support and weakening of pelvic tissues. Stress incontinence is also observed in men after prostatic surgery, most commonly radical prostatectomy, in which there may be injury to the external urethral sphincter. Stress urinary incontinence is difficult to manage pharmacologically, and patients with significant stress incontinence are usually best treated surgically.

Urgency Incontinence. Urgency incontinence is the precipitous loss of urine preceded by a strong urge to void. This symptom is commonly observed in patients with cystitis, neurogenic bladder, and advanced bladder outlet obstruction with secondary loss of bladder compliance. It is important to distinguish urgency incontinence from stress incontinence for two reasons. First, **urgency incontinence may result from a secondary underlying pathologic process, which should be identified;** treatment of this primary problem such as infection or bladder outlet obstruction may result in resolution of urgency incontinence. Second, patients with urgency incontinence are usually not amenable to surgical correction but, rather, are more appropriately treated with pharmacologic agents that increase bladder compliance and/or increase urethral resistance.

Overflow Urinary Incontinence. Overflow urinary incontinence, often called *paradoxical incontinence*, is secondary to advanced urinary retention and high residual urine volumes. In these patients, the bladder is chronically distended and never empties completely. Urine may dribble out in small amounts as the bladder overflows. This is particularly likely to occur at night when the patient is less likely to inhibit urinary leakage. **Overflow incontinence has been termed *paradoxical incontinence* because it can often be cured by relief of bladder outlet obstruction.** It is, however, often difficult to make the diagnosis of overflow incontinence by history and physical examination alone, particularly in the obese patient, in whom percussion of the distended bladder may be difficult. Overflow incontinence usually develops over a considerable length of time, and patients may be totally unaware of incomplete bladder emptying. Thus any patient with significant incontinence should undergo measurement of postvoid residual urine.

Enuresis. Enuresis refers to urinary incontinence that occurs during sleep. It occurs normally in children up to 3 years of age but persists in about 15% of children at age 5 and about 1% of children at age 15 (Forsythe and Redmond, 1974). Enuresis must be distinguished from continuous incontinence, which occurs in the day and night and which, in a young girl, usually indicates the presence of an ectopic ureter. All children older than age 6 years with enuresis should undergo a urologic evaluation, although the vast majority will be found to have no significant urologic abnormality.

Sexual Dysfunction

Male sexual dysfunction is frequently used synonymously with *impotence* or erectile dysfunction, although impotence refers specifically to the inability to achieve and maintain an erection adequate for intercourse. Patients presenting with "impotence" should be questioned carefully to rule out other male sexual disorders, including loss of libido, absence of emission, absence of orgasm, and, most commonly, premature ejaculation. It is important to identify the precise problem before proceeding with further evaluation and treatment.

Loss of Libido. Because androgens have a major influence on sexual desire, a decrease in libido may indicate androgen deficiency arising from either pituitary or testicular dysfunction. This can be evaluated directly by measurement of serum testosterone that, if abnormal, should be further evaluated by measurement of serum gonadotropins and prolactin. Because the amount of testosterone required to maintain libido is usually less than that required for full

stimulation of the prostate and seminal vesicles, patients with hypogonadism may also note decreased or absent ejaculation. Conversely, if semen volume is normal, it is unlikely that endocrine factors are responsible for loss of libido. A decrease in libido may also result from depression and a variety of medical illnesses that affect general health and well-being.

Impotence. Impotence refers specifically to the inability to achieve and maintain an erection sufficient for intercourse. A careful history will often determine whether the problem is primarily psychogenic or organic. In men with psychogenic impotence, the condition frequently develops rather quickly secondary to a precipitating event such as marital stress or change or loss of a sexual partner. In men with organic impotence, the condition usually develops more insidiously and frequently can be linked to advancing age or other underlying risk factors.

In evaluating men with impotence, it is important to determine whether the problem exists in all situations. Many men who report impotence may not be able to have intercourse with one partner but will with another. Similarly, it is important to determine whether men are able to achieve normal erections with alternative forms of sexual stimulation (e.g., masturbation, erotic videos). Finally, the patient should be asked whether he ever notes nocturnal or early morning erections. In general, **patients who are able to achieve adequate erections in some situations but not others have primarily psychogenic rather than organic impotence.**

Failure to Ejaculate. A failure to ejaculate may result from several causes: (1) androgen deficiency, (2) sympathetic denervation, (3) pharmacologic agents, and (4) bladder neck and prostatic surgery. Androgen deficiency results in decreased secretions from the prostate and seminal vesicles, causing a reduction or loss of seminal volume. Sympathectomy or extensive retroperitoneal surgery, most notably retroperitoneal lymphadenectomy for testicular cancer, may interfere with autonomic innervation of the prostate and seminal vesicles, resulting in absence of smooth muscle contraction and absence of seminal emission at time of orgasm. Pharmacologic agents, particularly α -adrenergic antagonists, may interfere with bladder neck closure at time of orgasm and result in retrograde ejaculation. Similarly, previous bladder neck or prostatic urethral surgery, most commonly transurethral resection of the prostate, may interfere with bladder neck closure, resulting in retrograde ejaculation. Finally, retrograde ejaculation may develop spontaneously in diabetic men.

Patients who complain of absence of ejaculation should be questioned regarding loss of libido or other symptoms of androgen deficiency, present medications, diabetes, and previous surgery. A careful history will usually determine the cause of this problem.

Absence of Orgasm. Anorgasmia is usually psychogenic or caused by certain medications used to treat psychiatric diseases. Sometimes, however, anorgasmia may be due to decreased penile sensation owing to impaired pudendal nerve function. Most commonly, this occurs in diabetics with peripheral neuropathy. Men who experience anorgasmia in association with decreased penile sensation should undergo vibratory testing of the penis and further neurologic evaluation as indicated.

Premature Ejaculation. Men who complain of premature ejaculation should be questioned carefully because this is obviously a subjective symptom. It is common for men to ejaculate within 2 minutes after initiation of intercourse, and many men who complain of premature ejaculation in actuality have normal sexual function with abnormal sexual expectations. However, there are men with true premature ejaculation who reach orgasm within less than 1 minute after initiation of intercourse. **This problem is almost always psychogenic** and best treated by a clinical psychologist or psychiatrist who specializes in treatment of this problem and other psychological aspects of male sexual dysfunction. With counseling and appropriate modifications in sexual technique, this problem can usually be overcome. Alternatively, treatment with serotonin reuptake inhibitors such as sertraline and fluoxetine has been demonstrated to be helpful in men with premature ejaculation (Murat Basar et al, 1999).

Hemospermia

Hemospermia refers to the presence of blood in the seminal fluid. **It almost always results from nonspecific inflammation of the prostate and/or seminal vesicles and resolves spontaneously, usually within several weeks.** It frequently occurs after a prolonged period of sexual abstinence, and we have observed it several times in men whose wives are in the final weeks of pregnancy. Patients with hemospermia that persists beyond several weeks should undergo further urologic evaluation because, rarely, an underlying etiology will be identified. A genital and rectal examination should be done to exclude the presence of tuberculosis; a prostate-specific antigen (PSA) and a rectal examination done to exclude prostatic carcinoma; and a urinary cytology done to exclude the possibility of transitional cell carcinoma of the prostate. It should be emphasized, however, that hemospermia almost always resolves spontaneously and rarely is associated with any significant urologic pathology.

Pneumaturia

Pneumaturia is the passage of gas in the urine. In patients who have not recently had urinary tract instrumentation or a urethral catheter placed, this is almost always due to a fistula between the intestine and the bladder. **Common causes include diverticulitis, carcinoma of the sigmoid colon, and regional enteritis (Crohn disease).** In rare instances, patients with diabetes mellitus may have gas-forming infections, with carbon dioxide formation from the fermentation of high concentrations of sugar in the urine.

Urethral Discharge

Urethral discharge is the most common symptom of venereal infection. A purulent discharge that is thick, profuse, and yellow to gray is typical of gonococcal urethritis; the discharge in patients with nonspecific urethritis is usually scant and watery. A bloody discharge is suggestive of carcinoma of the urethra.

Fever and Chills

Fever and chills may occur with infection anywhere in the GU tract but are most commonly observed in patients with pyelonephritis, prostatitis, or epididymitis. **When associated with urinary obstruction, fever and chills may portend septicemia and necessitate emergency treatment to relieve obstruction.**

Medical History

The past medical history is extremely important because it frequently provides clues to the patient's current diagnosis. The past medical history should be obtained in an orderly and sequential manner.

Previous Medical Illnesses with Urologic Sequelae

Many diseases may affect the GU system, and it is important to listen to the patient and record previous medical illnesses. **Patients with diabetes mellitus frequently develop autonomic dysfunction that may result in impaired urinary and sexual function.** A previous history of tuberculosis may be important in a patient presenting with impaired renal function, ureteral obstruction, or chronic, unexplained UTIs. Patients with hypertension have an increased risk of sexual dysfunction because they are more likely to have peripheral vascular disease and because many of the medications that are used to treat hypertension frequently cause impotence. Patients with neurologic diseases such as multiple sclerosis are also more likely to develop urinary and sexual dysfunction. In fact, 5% of patients with previously undiagnosed multiple sclerosis present with urinary symptoms as the first manifestation of the disease (Blaivas and Kaplan, 1988). As mentioned earlier, in men with bladder outlet obstruction, it is important to be aware of

preexisting neurologic conditions. Surgical treatment of bladder outlet obstruction in the presence of detrusor hyperreflexia may result in increased urinary incontinence postoperatively. Finally, patients with sickle cell anemia are prone to a number of urologic conditions, including papillary necrosis and erectile dysfunction secondary to recurrent priapism. There are many other diseases with urologic sequelae, and it is important for the urologist to take a careful history in this regard.

Family History

It is similarly important to obtain a detailed family history because many diseases are genetic and/or familial. Examples of genetic diseases include adult polycystic kidney disease, tuberous sclerosis, von Hippel-Lindau disease, renal tubular acidosis, and cystinuria; these are but a few common and well-recognized examples.

In addition to these diseases of known genetic predisposition, there are other conditions in which the precise pattern of inheritance has not been elucidated but that clearly have a familial tendency. It is well known that individuals with a family history of urolithiasis are at increased risk for stone formation. More recently, it has been recognized that **8% to 10% of men with prostate cancer have a familial form of the disease that tends to develop about a decade earlier than the more common type of prostate cancer (Bratt, 2000).** Other familial conditions are mentioned elsewhere in the text, but suffice it to state again that obtaining a careful history of previous illnesses and a family history of urologic disease can be extremely valuable in establishing the correct diagnosis.

Medications

It is similarly important to obtain an accurate and complete list of present medications because many drugs interfere with urinary and sexual function. **For example, most of the antihypertensive medications interfere with erectile function, and changing antihypertensive medications can sometimes improve sexual function.** Similarly, many of the psychotropic agents interfere with emission and orgasm. In our own recent experience, we cared for a man who presented with anorgasmia. He had been to several physicians without improvement in this problem. When we obtained his past medical history, he mentioned that he had been taking a psychotropic agent for transient depression for several years, and his anorgasmia resolved when this no-longer-needed medication was discontinued. The list of medications affecting urinary and sexual function is exhaustive, but, once again, each medication should be recorded and its side effects investigated to be sure that the patient's problem is not drug related. A listing of common medications that may cause urologic side effects is presented in [Table 1-2](#).

Previous Surgical Procedures

It is important to be aware of previous operations, particularly in a patient who may have surgery, because previous operations may make subsequent ones more difficult. If the previous surgery was in a similar anatomic region, it is worthwhile to try to obtain the previous operative report. In our own experience, this small additional effort has been rewarded on numerous occasions by providing a clear explanation of the patient's previous surgery that greatly simplified the subsequent operation. In general, **it is worthwhile to obtain as much information as possible before any intended surgery** because most surprises that occur in the operating room are unhappy ones.

Smoking and Alcohol Use

Cigarette smoking and consumption of alcohol are clearly linked to a number of urologic conditions. **Cigarette smoking is associated with an increased risk of urothelial carcinoma, most notably bladder cancer, and it is also associated with increased peripheral vascular disease and erectile dysfunction.** Chronic alcoholism may result in autonomic and peripheral neuropathy

TABLE 1-2 Drugs Associated with Urologic Side Effects

UROLOGIC SIDE EFFECTS	CLASS OF DRUGS	SPECIFIC EXAMPLES
Decreased libido	Antihypertensives	Hydrochlorothiazide
Erectile dysfunction	Psychotropic drugs	Propranolol Benzodiazepines
Ejaculatory dysfunction	α -Adrenergic antagonists	Prazosin Tamsulosin
	Psychotropic drugs	α -Methyl dopa Phenothiazines Antidepressants
Priapism	Antipsychotics Antidepressants Antihypertensives	Phenothiazines Trazodone Hydralazine Prazosin
Decreased spermatogenesis	Chemotherapeutic agents Drugs with abuse potential	Alkylating agents Marijuana Alcohol Nicotine
	Drugs affecting endocrine function	Antiandrogens Prostaglandins
Incontinence or impaired voiding	Direct smooth muscle stimulants	Histamine Vasopressin
	Others	Furosemide Valproic acid
	Smooth muscle relaxants Striated muscle relaxants	Diazepam Baclofen
Urinary retention or obstructive voiding symptoms	Anticholinergic agents or musculotropic relaxants	Oxybutynin Diazepam Flavoxate
	Calcium channel blockers Antiparkinsonian drugs	Nifedipine Carbidopa Levodopa
	α -Adrenergic agonists	Pseudoephedrine Phenylephrine
	Antihistamines	Loratadine Diphenhydramine
Acute renal failure	Antimicrobials	Aminoglycosides Penicillins Cephalosporins Amphotericin
	Chemotherapeutic drugs Others	Cisplatin Nonsteroidal anti-inflammatory drugs Phenytoin
Gynecomastia	Antihypertensives Cardiac drugs Gastrointestinal drugs	Verapamil Digoxin Cimetidine Metoclopramide
	Psychotropic drugs Tricyclic antidepressants	Phenothiazines Amitriptyline Imipramine

with resultant impaired urinary and sexual function. Chronic alcoholism may also impair hepatic metabolism of estrogens, resulting in decreased serum testosterone, testicular atrophy, and decreased libido.

In addition to the direct urologic effects of cigarette smoking and alcohol consumption, patients who are actively smoking or drinking up to the time of surgery are at increased risk for perioperative complications. Smokers are at increased risk for both pulmonary and cardiac complications. If possible, they should **discontinue smoking at least 8 weeks before surgery to optimize their**

pulmonary function (Warner et al, 1989). If they are unable to do this, they should at least quit smoking for 48 hours before surgery because this will result in a significant improvement in cardiovascular function. Similarly, chronic alcoholics are at increased risk for hepatic toxicity and subsequent coagulation problems postoperatively. Furthermore, alcoholics who continue drinking up to the time of surgery may experience acute alcohol withdrawal during the postoperative period that can be life threatening. Prophylactic administration of lorazepam (Ativan) greatly reduces the potential risk of this significant complication.

Allergies

Finally, medicinal allergies should be questioned because these medications should be avoided in future treatment of the patient. **All medicinal allergies should be marked boldly on the front of the patient's chart** to avoid potential complications from inadvertent exposure to the same medications.

In summary, a careful and thorough medical history including the chief complaint and history of present illness, past medical history, and family history should be obtained for every patient. Unfortunately, time constraints often make it difficult for the physician to spend the necessary time to obtain a full history. A reasonable substitute is to have a trained nurse or other health professional see the patient first. By using a standard history form, much of the information discussed previously can be obtained in a preliminary interview. It then remains for the urologist to only fill in the blanks, have the patient elaborate on potentially relevant aspects of the past medical history, and then perform a complete physical examination.

PHYSICAL EXAMINATION

KEY POINTS

- The urologist can undertake the initial evaluation and establish a diagnosis for almost all patients with diseases of the GU system.
- A complete history and appropriate physical examination is critical in the assessment of urologic patients.
- A complete urinalysis including chemical and microscopic analyses should be performed because this may provide important information critical to the diagnosis and treatment of urologic patients.

A complete and thorough physical examination is an essential component of the evaluation of patients who present with urologic disease. Although it is tempting to become dependent on results of laboratory and radiologic tests, **the physical examination often simplifies the process and allows the urologist to select the most appropriate diagnostic studies.** Along with the history, the physical examination remains a key component of the diagnostic evaluation and should be performed conscientiously.

General Observations

The visual inspection of the patient provides a general overview. The skin should be inspected for evidence of jaundice or pallor. The nutritional status of the patient should be noted. **Cachexia is a frequent sign of malignancy, and obesity may be a sign of underlying endocrinologic abnormalities.** In this instance, one should search for the presence of truncal obesity, a "buffalo hump," and abdominal skin striae, which are stigmata of hyperadrenocorticism. In contrast, debility and hyperpigmentation may be signs of hypoadrenocorticism. Gynecomastia may be a sign of endocrinologic disease and a possible indicator of alcoholism or previous hormonal therapy for prostate cancer. Edema of the genitalia and lower extremities may be associated with cardiac decompensation, renal failure, nephrotic syndrome, or pelvic and/or retroperitoneal lymphatic obstruction. Supraclavicular lymphadenopathy may be seen with any GU neoplasm, most commonly prostate and testis cancer; inguinal lymphadenopathy may occur secondary to carcinoma of the penis or urethra.

Kidneys

The kidneys are fist-sized organs located high in the retroperitoneum bilaterally. In the adult, the kidneys are normally difficult to

palpate because of their position under the diaphragm and ribs with abundant musculature both anteriorly and posteriorly. Because of the position of the liver, the right kidney is somewhat lower than the left. **In children and thin women, it may be possible to palpate the lower pole of the right kidney with deep inspiration.** However, it is usually not possible to palpate either kidney in men, and the left kidney is almost always impalpable unless it is abnormally enlarged.

The best way to palpate the kidneys is with the patient in the supine position. **The kidney is lifted from behind with one hand in the costovertebral angle (Fig. 1-1).** On deep inspiration, the examiner's hand is advanced firmly into the anterior abdomen just below the costal margin. At the point of maximal inspiration, the kidney may be felt as it moves downward with the diaphragm. With each inspiration, the examiner's hand may be advanced deeper into the abdomen. Once again, it is more difficult to palpate kidneys in men because the kidneys tend to move downward less with inspiration and because they are surrounded with thicker muscular layers. In children, it is easier to palpate the kidneys because of decreased body thickness. In neonates, the kidneys can be felt quite easily by palpating the flank between the thumb anteriorly and the fingers over the costovertebral angle posteriorly.

Transillumination of the kidneys may be helpful in children younger than 1 year of age with a palpable flank mass. Such masses are frequently of renal origin. A flashlight or fiberoptic light source is positioned posteriorly against the costovertebral angle. Fluid-filled masses such as cysts or hydronephrosis produce a dull reddish glow in the anterior abdomen. Solid masses such as tumors do not transilluminate. Other diagnostic maneuvers that may be helpful in examining the kidneys are percussion and auscultation. Although renal inflammation may cause pain that is poorly localized, percussion of the costovertebral angle posteriorly more often localizes the pain and tenderness more accurately. Percussion should be done gently because in a patient with significant renal inflammation, this may be quite painful. Auscultation of the upper abdomen during deep inspiration may occasionally reveal a systolic bruit associated with renal artery stenosis or an aneurysm. A bruit may also be detected in association with a large renal arteriovenous fistula.

Every patient with flank pain should also be examined for possible nerve root irritation. The ribs should be palpated carefully to rule out a bone spur or other skeletal abnormality and to determine the point of maximal tenderness. Unlike renal pain, radiculitis usually causes hyperesthesia of the overlying skin innervated by the irritated peripheral nerve. This hypersensitivity can be elicited with a pin or by pinching the skin and fat overlying the involved area. Finally, the pain experienced during the pre-eruptive phase of herpes zoster involving any of the segments between T11 and L2 may also simulate pain of renal origin.

Figure 1-1. Bimanual examination of the kidney.

Bladder

A normal bladder in the adult cannot be palpated or percussed until there is at least 150 mL of urine in it. At a volume of about 500 mL, the distended bladder becomes visible in thin patients as a lower midline abdominal mass.

Percussion is better than palpation for diagnosing a distended bladder. The examiner begins by percussing immediately above the symphysis pubis and continuing cephalad until there is a change in pitch from dull to resonant. Alternatively, it may be possible in thin patients and in children to palpate the bladder by lifting the lumbar spine with one hand and pressing the other hand into the midline of the lower abdomen.

A careful bimanual examination, best done with the patient under anesthesia, is invaluable in assessing the regional extent of a bladder tumor or other pelvic mass. The bladder is palpated between the abdomen and the vagina in the female (Fig. 1-2) or the rectum in the male (Fig. 1-3). In addition to defining areas of induration, the bimanual examination allows the examiner to assess the mobility of the bladder; such information cannot be obtained by radiologic techniques such as CT and MRI, which convey static images.

Penis

If the patient has not been circumcised, the foreskin should be retracted to examine for tumor or balanoposthitis (inflammation of the prepuce and glans penis). **Most penile cancers occur in uncircumcised men and arise on the prepuce or glans penis.** Therefore in a patient with a bloody penile discharge in whom the foreskin cannot be withdrawn, a dorsal slit or circumcision must be performed to adequately evaluate the glans penis and urethra.

Figure 1-2. Bimanual examination of the bladder in the female. (From Swartz MH. Textbook of physical diagnosis. Philadelphia: Saunders; 1989. p. 405.)

The position of the urethral meatus should be noted. It may be located proximal to the tip of the glans on the ventral surface (hypospadias) or, much less commonly, on the dorsal surface (epispadias). The penile skin should be examined for the presence of superficial vesicles compatible with herpes simplex and for ulcers that may indicate either venereal infection or tumor. The presence of venereal warts (condylomata acuminata), which appear as irregular, papillary, velvety lesions on the male genitalia, should also be noted.

The urethral meatus should be separated between the thumb and the forefinger to inspect for neoplastic or inflammatory lesions within the fossa navicularis. The dorsal shaft of the penis should be palpated for the presence of fibrotic plaques or ridges typical of Peyronie disease. Tenderness along the ventral aspect of the penis is suggestive of periurethritis, often secondary to a urethral stricture.

Scrotum and Contents

The scrotum is a loose sac containing the testes and spermatic cord structures. The scrotal wall is made up of skin and an underlying thin muscular layer. The testes are normally oval, firm, and smooth; in adults, they measure about 6 cm in length and 4 cm in width. They are suspended in the scrotum, with the right testis normally anterior to the left. The epididymis lies posterior to the testis and is palpable as a distinct ridge of tissue. The vas deferens can be palpated above each testis and feels like a piece of heavy twine.

The scrotum should be examined for dermatologic abnormalities. **Because the scrotum, unlike the penis, contains both hair and sweat glands, it is a frequent site of local infection and sebaceous cysts.** Hair follicles can become infected and may present as small pustules on the surface of the scrotum. These usually resolve spontaneously, but they can give rise to more significant infection, particularly in patients with reduced immunity and diabetes. Patients often become concerned about these lesions, mistaking them for testicular tumors.

The testes should be palpated gently between the fingertips of both hands. The testes normally have a firm, rubbery consistency with a smooth surface. Abnormally small testes suggest hypogonadism or an endocrinopathy such as Klinefelter disease. **A firm or hard area within the testis should be considered a malignant tumor until proved otherwise.** The epididymis should be palpable as a ridge posterior to each testis. Masses in the epididymis (spermatocele, cyst, and epididymitis) are almost always benign.

To examine for a hernia, the physician's index finger should be inserted gently into the scrotum and invaginated into the external inguinal ring (Fig. 1-4). The scrotum should be

Figure 1-3. Bimanual examination of the bladder in the male.

Figure 1-4. Examination of the inguinal canal. (From Swartz MH. *Textbook of physical diagnosis*. Philadelphia: Saunders; 1989. p. 376.)

invaginated in front of the testis, and care should be taken not to elevate the testis itself, which is quite painful. Once the external ring has been located, the physician should place the fingertips of his or her other hand over the internal inguinal ring and ask the patient to bear down (Valsalva maneuver). A hernia will be felt as a distinct bulge that descends against the tip of the index finger in the external inguinal ring as the patient bears down. Although it may be possible to distinguish a direct inguinal hernia arising through the floor of the inguinal canal from an indirect inguinal hernia prolapsing through the internal inguinal ring, this is seldom possible and of little clinical significance because the surgical approach is essentially identical for both conditions.

The spermatic cord is also examined with the patient in the standing position. A varicocele is a dilated, tortuous spermatic vein that becomes more obvious as the patient performs a Valsalva maneuver. The epididymis can again be palpated as a ridge of tissue running longitudinally, posterior to each testis. The testis should be palpated again between the fingers of both hands, once again taking care not to exert any pressure on the testis itself so as to avoid pain.

Transillumination is helpful in determining whether scrotal masses are solid (tumor) or cystic (hydrocele, spermatocele). A small flashlight or fiberoptic light cord is placed behind the mass. A cystic mass transilluminates easily, whereas light is not transmitted through a solid tumor.

Rectal and Prostate Examination in the Male

Digital rectal examination (DRE) should be performed in every male after age 40 years and in men of any age who present for urologic evaluation. Prostate cancer is the second most common cause of male cancer deaths after age 55 years and the most common cause of cancer deaths in men older than 70 years. Many prostate cancers can be detected in an early curable stage by DRE, and about 25% of colorectal cancers can be detected by DRE in combination with a stool guaiac test.

DRE should be performed at the end of the physical examination. It is done best with the patient standing and bent over the examining table or with the patient in the knee-chest position. In

the standing position, the patient should stand with his thighs close to the examining table. The feet should be about 18 inches apart, with the knees flexed slightly. The patient should bend at the waist 90 degrees until his chest is resting on his forearms. The physician should give the patient adequate time to get in the proper position and relax as much as possible. A few reassuring words before the examination are helpful. The physician should place a glove on the examining hand and should lubricate the index finger thoroughly.

Before performing the DRE, the physician should place the palm of his other hand against the patient's lower abdomen. This provides subtle reassurance to the patient by allowing the physician to make gentle contact with the patient before touching the anus. It also allows the physician to steady the patient and provide gentle counterpressure if the patient tries to move away as the DRE is being performed. The DRE itself begins by separating the buttocks and inspecting the anus for pathology, usually hemorrhoids, but, occasionally, an anal carcinoma or melanoma may be detected. The gloved, lubricated index finger is then inserted gently into the anus. Only one phalanx should be inserted initially to give the anus time to relax and to easily accommodate the finger. Estimation of anal sphincter tone is of great importance; a flaccid or spastic anal sphincter suggests similar changes in the urinary sphincter and may be a clue to the diagnosis of neurogenic disease. If the physician waits only a few seconds, the anal sphincter will normally relax to the degree that the finger can be advanced to the knuckle without causing pain. The index finger then sweeps over the prostate; the entire posterior surface of the gland can usually be examined if the patient is in the proper position. **Normally, the prostate is about the size of a chestnut and has a consistency similar to that of the contracted thenar eminence of the thumb (with the thumb opposed to the little finger).**

The index finger is extended as far as possible into the rectum, and the entire circumference is examined to detect an early rectal carcinoma. The index finger is then withdrawn gently, and the stool on the glove is transferred to a guaiac-impregnated (Hemoccult) card for determination of occult blood. Although there may be a significant incidence of false-positive and false-negative results associated with fecal occult blood testing, particularly without dietary and drug restrictions, **the guaiac test is simple and inexpensive and may lead to the detection of significant gastrointestinal abnormalities (Bond, 1999).** Adequate tissues, soap, and towels should be available for the patient to cleanse himself after the examination. The physician should then leave the room and allow the patient adequate time to wash and dress before concluding the consultation.

Pelvic Examination in the Female

Male urologists should always perform the female pelvic examination with a female nurse or other health care professional present. The patient should be allowed to undress in privacy and be fully draped for the procedure before the physician enters the room. The examination itself should be performed in standard lithotomy position with the patient's legs abducted. Initially, the external genitalia and introitus should be examined, with particular attention paid to atrophic changes, erosions, ulcers, discharge, or warts, all of which may cause dysuria and pelvic discomfort. The urethral meatus should be inspected for caruncles, mucosal hyperplasia, cysts, and mucosal prolapse. The patient is then asked to perform a Valsalva maneuver and is carefully examined for a cystocele (prolapse of the bladder) or rectocele (prolapse of the rectum). The patient is then asked to cough, which may precipitate stress urinary incontinence. Palpation of the urethra is done to detect induration, which may be a sign of chronic inflammation or malignancy. Palpation may also disclose a urethral diverticulum, and palpation of a diverticulum may cause a purulent discharge from the urethra. Bimanual examination of the bladder, uterus, and adnexa should then be performed with two fingers in the vagina and the other hand on the lower abdomen. Any abnormality of the pelvic organs should be evaluated further with a pelvic ultrasound or CT scan.

Figure 1-5. Sensory dermatome maps used to help localize the level of neurologic deficit.

Neurologic Examination

There are various clinical situations in which the neurologic examination may be helpful in evaluating urologic patients. In some cases, the level of neurologic abnormalities can be localized by the pattern of sensory deficit noted during physical examination using a dermatome map (Fig. 1-5). Sensory deficits in the penis, labia, scrotum, vagina, and perianal area generally indicate damage or injury to sacral roots or nerves. In addition to sensory examination, testing of reflexes in the genital area may also be performed. The most important of these is the bulbocavernosus reflex (BCR), which is a reflex contraction of the striated muscle of the pelvic floor that occurs in response to various stimuli in the perineum or genitalia. This reflex is most commonly tested by placing a finger in the rectum and then squeezing the glans penis or clitoris. If a Foley catheter is in place, the BCR can also be elicited by gently pulling on the catheter. If the BCR is intact, tightening of the anal sphincter should be felt and/or observed. The BCR tests the integrity of the spinal cord-mediated reflex arc involving S2-S4 and may be absent in the presence of sacral cord or peripheral nerve abnormalities.

The cremasteric reflex can be elicited by lightly stroking the superior and medial thigh in a downward direction. The normal response in males is contraction of the cremasteric muscle that results in immediate elevation of the ipsilateral scrotum and testis. There is limited clinical utility for testing superficial reflexes such as the cremasteric when investigating neurologic dysfunction. However, there may be a role for testing this reflex when assessing patients with suspected testicular torsion or epididymitis. Finally, an overly active cremasteric reflex in children can lead to the mistaken diagnosis of an undescended testis in some cases.

URINALYSIS

The urinalysis is a fundamental test that should be performed in all urologic patients. Although in many instances a simple dipstick

urinalysis will provide the necessary information, a complete urinalysis includes both chemical and microscopic analyses.

Collection of Urinary Specimens

Males

In the male patient, a midstream urine sample is obtained. The uncircumcised male should retract the foreskin, cleanse the glans penis with antiseptic solution, and continue to retract the foreskin during voiding. The male patient begins urinating into the toilet and then places a wide-mouth sterile container under his penis to collect a midstream sample. This avoids contamination of the urine specimen with skin and urethral organisms.

In men with chronic UTIs, four aliquots of urine are obtained. These aliquots have been designated **Voided Bladder 1, Voided Bladder 2, Expressed Prostatic Secretions, and Voided Bladder 3 (VB1, VB2, EPS, and VB3)**. The VB1 is the initial 5 to 10 mL of urine voided, whereas the VB2 is the midstream urine. The EPS is the secretions obtained after gentle prostatic massage, and the VB3 specimen is the initial 2 to 3 mL of urine obtained after prostatic massage. The value of these cultures for localization of UTIs is that the VB1 sample represents urethral flora; the VB2, bladder flora; and the EPS and VB3 samples, prostatic flora. The VB3 sample is particularly helpful when little or no prostatic fluid is obtained by massage. To better obtain prostatic secretions, patients should be instructed to attempt to void during prostatic massage and to avoid tightening the anal sphincter and pelvic floor muscles. The four-part urine sample is particularly useful in evaluating men with suspected bacterial prostatitis (Meares and Stamey, 1968).

Females

In the female, it is more difficult to obtain a clean-catch midstream specimen. The female patient should cleanse the vulva, separate the labia, and collect a midstream specimen as described for the male

patient. If infection is suspected, however, the midstream specimen is unreliable and should never be sent for culture and sensitivity. To evaluate for a possible infection in a female, a catheterized urine sample should always be obtained.

Neonates and Infants

The usual way to obtain a urine sample in a neonate or infant is to place a sterile plastic bag with an adhesive collar over the infant's genitalia. However, these devices may not be able to distinguish contamination from true UTI. Whenever possible, **all urine samples should be examined within 1 hour of collection and plated for culture and sensitivity if indicated.** If urine is allowed to stand at room temperature for longer periods of time, bacterial overgrowth may occur, the pH may change, and red and white blood cell casts may disintegrate. If it is not possible to examine the urine promptly, it should be refrigerated at 5°C.

Physical Examination of Urine

The physical examination of the urine includes an evaluation of color, turbidity, specific gravity and osmolality, and pH.

Color

The normal pale yellow color of urine is due to the presence of the pigment urochrome. **Urine color varies most commonly because of concentration, but many foods, medications, metabolic products, and infection may produce abnormal urine color.** This is important because many patients will seek consultation primarily because of a change in their urine color. Thus it is important for the urologist to be aware of the common causes of abnormal urine color, and these are listed in Table 1-3.

Turbidity

Freshly voided urine is clear. **Cloudy urine is most commonly due to phosphaturia**, a benign process in which excess phosphate crystals precipitate in an alkaline urine. Phosphaturia is intermittent and usually occurs after meals or ingestion of a large quantity of milk. Patients are otherwise asymptomatic. The diagnosis of phosphaturia can be accomplished either by acidifying the urine with acetic acid, which will result in immediate clearing, or by performing a microscopic analysis, which will reveal large amounts of amorphous phosphate crystals.

Pyuria, usually associated with a UTI, is another common cause of cloudy urine. The large numbers of white blood cells cause the urine to become turbid. **Pyuria is readily distinguished from phosphaturia either by smelling the urine (infected urine has a characteristic pungent odor) or by microscopic examination, which readily distinguishes amorphous phosphate crystals from leukocytes.**

Rare causes of cloudy urine include chyluria (in which there is an abnormal communication between the lymphatic system and the urinary tract resulting in lymph fluid being mixed with urine), lipiduria, hyperoxaluria, and hyperuricosuria.

Specific Gravity and Osmolality

Specific gravity of urine is easily determined from a urinary dipstick and usually varies from 1.001 to 1.035. Specific gravity usually reflects the patient's state of hydration but may also be affected by abnormal renal function, the amount of material dissolved in the urine, and a variety of other causes mentioned later. A specific gravity less than 1.008 is regarded as dilute, and a specific gravity greater than 1.020 is considered concentrated. A fixed specific gravity of 1.010 is a sign of renal insufficiency, either acute or chronic.

In general, specific gravity reflects the state of hydration but also affords some idea of renal concentrating ability. Conditions that decrease specific gravity include (1) increased fluid intake,

TABLE 1-3 Common Causes of Abnormal Urine Color

COLOR	CAUSE
Colorless	Very dilute urine Overhydration
Cloudy/milky	Phosphaturia Pyuria Chyluria
Red	Hematuria Hemoglobinuria/myoglobinuria Anthocyanin in beets and blackberries Chronic lead and mercury poisoning Phenolphthalein (in bowel evacuants) Phenothiazines (e.g., Compazine) Rifampin
Orange	Dehydration Phenazopyridine (Pyridium) Sulfasalazine (Azulfidine)
Yellow	Normal Phenacetin Riboflavin
Green-blue	Biliverdin Indicanuria (tryptophan indole metabolites) Amitriptyline (Elavil) Indigo carmine Methylene blue Phenols (e.g., IV cimetidine [Tagamet], IV promethazine [Phenergan]) Resorcinol Triamterene (Dyrenium)
Brown	Urobilinogen Porphyria Aloe, fava beans, and rhubarb Chloroquine and primaquine Furazolidone (Furoxone) Metronidazole (Flagyl) Nitrofurantoin (Furadantin)
Brown-black	Alcaptonuria (homogentisic acid) Hemorrhage Melanin Tyrosinosis (hydroxyphenylpyruvic acid) Cascara, senna (laxatives) Methocarbamol (Robaxin) Methyldopa (Aldomet) Sorbitol

IV, intravenous.

From Hanno PM, Wein AJ. A clinical manual of urology. Norwalk (CT): Appleton-Century-Crofts; 1987. p. 67.

(2) diuretics, (3) decreased renal concentrating ability, and (4) diabetes insipidus. Conditions that increase specific gravity include (1) decreased fluid intake; (2) dehydration owing to fever, sweating, vomiting, and diarrhea; (3) diabetes mellitus (glucosuria); and (4) inappropriate secretion of antidiuretic hormone. Specific gravity will also be increased above 1.035 after IV injection of iodinated contrast and in patients taking dextran.

Osmolality is a measure of the amount of material dissolved in the urine and usually varies between 50 and 1200 mOsm/L. Urine osmolality most commonly varies with hydration, and the same factors that affect specific gravity will also affect osmolality. Urine osmolality is a better indicator of renal function, but it cannot

be measured from a dipstick and must be determined using standard laboratory techniques.

pH

Urinary pH is measured with a dipstick test strip that incorporates two colorimetric indicators, methyl red and bromothymol blue, which yield clearly distinguishable colors over the pH range from 5 to 9. Urinary pH may vary from 4.5 to 8; the average pH varies between 5.5 and 6.5. A urinary pH between 4.5 and 5.5 is considered acidic, whereas a pH between 6.5 and 8 is considered alkaline.

In general, the urinary pH reflects the pH in the serum. In patients with metabolic or respiratory acidosis, the urine is usually acidic; conversely, in patients with metabolic or respiratory alkalosis, the urine is alkaline. Renal tubular acidosis (RTA) presents an exception to this rule. In patients with both type I and II RTA, the serum is acidemic, but the urine is alkalotic because of continued loss of bicarbonate in the urine. In severe metabolic acidosis in type II RTA, the urine may become acidic, but in type I RTA, the urine is always alkaline, even with severe metabolic acidosis (Morris and Ives, 1991). Urinary pH determination is used to establish the diagnosis of RTA; inability to acidify the urine below a pH of 5.5 after administration of an acid load is diagnostic of RTA.

Urine pH determinations are also useful in the diagnosis and treatment of UTIs and urinary calculus disease. **In patients with a presumed UTI, an alkaline urine with a pH greater than 7.5 suggests infection with a urea-splitting organism, most commonly *Proteus*.** Urease-producing bacteria convert ammonia to ammonium ions, markedly elevating the urinary pH and causing precipitation of calcium magnesium ammonium phosphate crystals. The massive amount of crystallization may result in staghorn calculi.

Urinary pH is usually acidic in patients with uric acid and cystine lithiasis. Alkalinization of the urine is an important feature of therapy in both of these conditions, and frequent monitoring of urinary pH is necessary to ascertain adequacy of therapy.

Chemical Examination of Urine

Urine Dipsticks

Urine dipsticks provide a quick and inexpensive method for detecting abnormal substances within the urine. Dipsticks are short, plastic strips with small marker pads that are impregnated with different chemical reagents that react with abnormal substances in the urine to produce a colorimetric change. **The abnormal substances commonly tested for with a dipstick include (1) blood, (2) protein, (3) glucose, (4) ketones, (5) urobilinogen and bilirubin, and (6) white blood cells.**

Substances listed in Table 1-3 that produce an abnormal urine color may interfere with appropriate color development on the dipstick. In our experience, this most commonly occurs in patients taking phenazopyridine (Pyridium) for a UTI. Phenazopyridine turns the urine bright orange and makes dipstick evaluation of the urine unreliable.

Appropriate technique must be used to obtain an accurate dipstick determination. The reagent areas on the dipstick must be completely immersed in a fresh uncentrifuged urine specimen and then must be withdrawn immediately to prevent dissolution of the reagents into the urine. As the dipstick is removed from the urine specimen container, the edge of the dipstick is drawn along the rim of the container to remove excess urine. The dipstick should be held horizontally until the appropriate time for reading and then compared with the color chart. **Excess urine on the dipstick or holding the dipstick in a vertical position will allow mixing of chemicals from adjacent reagent pads on the dipstick, resulting in a faulty diagnosis.** False-negative results for glucose and bilirubin may be seen in the presence of elevated ascorbic acid concentrations in the

urine. However, increased levels of ascorbic acid in the urine do not interfere with dipstick testing for hematuria. Highly buffered alkaline urine may cause falsely low readings for specific gravity and may lead to false-negative results for urinary protein. Other common causes of false results with dipstick testing are outdated test strips and exposure of the sticks, leading to damage to the reagents. In general, when the sticks are damaged, there will be color changes on the pads before their immersion in urine. If such color changes are noted, results with the dipstick may be inaccurate.

Hematuria

Normal urine should contain fewer than three RBCs per HPF. A positive dipstick for blood in the urine indicates either hematuria, hemoglobinuria, or myoglobinuria. **The chemical detection of blood in the urine is based on the peroxidase-like activity of hemoglobin.** When in contact with an organic peroxidase substrate, hemoglobin catalyzes the reaction and causes subsequent oxidation of a chromogen indicator, which changes color according to the degree and amount of oxidation. The degree of color change is directly related to the amount of hemoglobin present in the urine specimen. Dipsticks frequently demonstrate both colored dots and field color change. If present, free hemoglobin and myoglobin in the urine are absorbed into the reagent pad and catalyze the reaction within the test paper, thereby producing a field change effect in color. Intact erythrocytes in the urine undergo hemolysis when they come in contact with the reagent test pad, and the localized free hemoglobin on the pad produces a corresponding dot of color change. The greater the number of intact erythrocytes in the urine specimen, the greater the number of dots that will appear on the test paper, and a coalescence of the dots occurs when there are more than 250 erythrocytes/mL.

Hematuria can be distinguished from hemoglobinuria and myoglobinuria by microscopic examination of the centrifuged urine; the presence of a large number of erythrocytes establishes the diagnosis of hematuria. If erythrocytes are absent, examination of the serum will distinguish hemoglobinuria and myoglobinuria. A sample of blood is obtained and centrifuged. In hemoglobinuria, the supernatant will be pink. This is because free hemoglobin in the serum binds to haptoglobin, which is water insoluble and has a high molecular weight. This complex remains in the serum, causing a pink color. Free hemoglobin will appear in the urine only when all of the haptoglobin-binding sites have been saturated. In myoglobinuria, the myoglobin released from muscle is of low molecular weight and water soluble. It does not bind to haptoglobin and is therefore excreted immediately into the urine. Therefore in myoglobinuria the serum remains clear.

The sensitivity of urinary dipsticks in identifying hematuria, defined as greater than three erythrocytes/HPF of centrifuged sediment examined microscopically, is higher than 90%. Conversely, the specificity of the dipstick for hematuria compared with microscopy is somewhat lower, reflecting a higher false-positive rate with the dipstick (Shaw et al, 1985).

False-positive dipstick readings are most often due to contamination of the urine specimen with menstrual blood. Dehydration with resultant urine of high specific gravity can also yield false-positive results owing to the increased concentration of erythrocytes and hemoglobin. The normal individual excretes about 1000 erythrocytes/mL of urine, with the upper limits of normal varying from 5000 to 8000 erythrocytes/mL (Kincaid-Smith, 1982). Therefore examining urine of high specific gravity such as the first morning voided specimen increases the likelihood of a false-positive result. In addition to dehydration, another cause of false-positive results is exercise, which can increase the number of erythrocytes in the urine.

The efficacy of hematuria screening using the dipstick to identify patients with significant urologic disease is somewhat controversial. Studies in children and young adults have shown a low rate of significant disease (Woolhandler et al, 1989). In older adults, one study from the Mayo Clinic of 2000 patients with asymptomatic hematuria showed that only 0.5% had a urologic

malignancy and only 1.8% developed other serious urologic diseases within 3 years after identification of the hematuria (Mohr et al, 1986). Conversely, investigators at the University of Wisconsin found that 26% of adults who had at least one positive dipstick reading for hematuria were subsequently found to have significant urologic pathology (Messing et al, 1987). The age of the population, the completeness of the subsequent urologic evaluation, and the definition of significant disease all influence the disease rate in the group of patients with asymptomatic hematuria identified by dipstick screening. It is important to remember that, before proceeding to more complicated studies, the dipstick result should be confirmed with a microscopic examination of the centrifuged urinary sediment.

Differential Diagnosis and Evaluation of Hematuria. Hematuria may reflect either significant nephrologic or urologic disease. Hematuria of nephrologic origin is frequently associated with casts in the urine and almost always associated with significant proteinuria. Even significant hematuria of urologic origin will not elevate the protein concentration in the urine into the 100 to 300 mg/dL or 2+ to 3+ range on dipstick, and proteinuria of this magnitude almost always indicates glomerular or tubulointerstitial renal disease.

Morphologic evaluation of erythrocytes in the centrifuged urinary sediment also helps localize their site of origin. Erythrocytes arising from glomerular disease are typically dysmorphic and show a wide range of morphologic alterations. Conversely, erythrocytes arising from tubulointerstitial renal disease and of urologic origin have a uniformly round shape; these erythrocytes may or may not retain their hemoglobin ("ghost cells"), but the individual cell shape is consistently round. In individuals without significant pathology with minimal amounts of hematuria, the erythrocytes are characteristically dysmorphic but the number of cells observed is far fewer than that observed in patients with nephrologic disease. Erythrocyte morphology is more easily determined using phase contrast microscopy, but with practice this can be accomplished using a conventional light microscope (Schramek et al, 1989).

Glomerular Hematuria. Glomerular hematuria is suggested by the presence of dysmorphic erythrocytes, RBC casts, and proteinuria. Of those patients with glomerulonephritis proven by renal biopsy, however, about 20% will have hematuria alone without RBC casts or proteinuria (Fassett et al, 1982).

The glomerular disorders associated with hematuria are listed in Table 1-4. Further evaluation of patients with glomerular hematuria should begin with a thorough history. Hematuria in children and

young adults, usually males, associated with low-grade fever and an erythematous rash suggests a diagnosis of immunoglobulin A (IgA) nephropathy (Berger disease). A family history of renal disease and deafness suggests familial nephritis or Alport syndrome. Hemoptysis and abnormal bleeding associated with microcytic anemia are characteristic of Goodpasture syndrome, and the presence of a rash and arthritis suggest systemic lupus erythematosus. Finally, post-streptococcal glomerulonephritis should be suspected in a child with a recent streptococcal upper respiratory tract or skin infection.

Further laboratory evaluation should include measurement of serum creatinine, creatinine clearance, and, when proteinuria in the urine is 2+ or greater, a 24-hour urine protein determination. Although these tests will quantitate the specific degree of renal dysfunction, further tests are usually required to establish the specific diagnosis and particularly to determine whether the disease is due to an immune or a nonimmune etiology. Frequently, a renal biopsy is necessary to establish the precise diagnosis, and biopsies are particularly important if the result will influence subsequent treatment of the patient. Renal biopsies are extremely informative when examined by an experienced pathologist using light, immunofluorescent, and electron microscopy.

An algorithm for the evaluation of glomerular hematuria is provided in Figure 1-6.

IgA Nephropathy (Berger Disease). IgA nephropathy, or Berger disease, is the most common cause of glomerular hematuria, accounting for about 30% of cases (Fassett et al, 1982). Therefore it is described in greater detail in this section. IgA nephropathy occurs most commonly in children and young adults, with a male predominance (Berger and Hinglais, 1968). Patients typically present with hematuria after an upper respiratory tract infection or exercise. Hematuria may be associated with a low-grade fever or rash, but most patients have no associated systemic symptoms. Gross hematuria occurs intermittently, but microscopic hematuria is a constant finding in some patients. The disease is chronic, but the prognosis in most patients is excellent. Renal function remains normal in the majority, but about 25% will subsequently develop renal insufficiency. An older age at onset, initial abnormal renal function, consistent proteinuria, and hypertension are indicators of a poor prognosis (D'Amico, 1988).

The pathologic findings in Berger disease are limited to either focal glomeruli or lobular segments of a glomerulus. The changes are proliferative and usually confined to mesangial cells (Berger and Hinglais, 1968). Renal biopsy reveals deposits of IgA, IgG, and β_2 -microglobulin, although IgA and IgG mesangial deposits are found in other forms of glomerulonephritis as well. The role of IgA in the disease remains uncertain, although the deposits may trigger an inflammatory reaction within the glomerulus (van den Wall Bake et al, 1989). Because gross hematuria frequently follows an upper respiratory tract infection, a viral etiology has been suspected but not established. The frequent association between hematuria and exercise in this condition remains unexplained.

The clinical presentation of IgA glomerulonephritis is alarming and similar to certain systemic diseases, including Schönlein-Henoch purpura, systemic lupus erythematosus, bacterial endocarditis, and Goodpasture syndrome. Therefore a careful clinical and laboratory evaluation is indicated to establish the correct diagnosis. The presence of RBC casts establishes the glomerular origin of the hematuria. In the absence of casts, a urologic evaluation is indicated to exclude the urinary tract as a source of bleeding and to confirm that the hematuria is arising from both kidneys. The diagnosis of IgA nephropathy is confirmed by renal biopsy demonstrating the classic deposits of immunoglobulins in mesangial cells, as described previously. Once the diagnosis has been established, repeat evaluations for hematuria are generally not indicated. Although there is no effective treatment for this condition, renal function remains stable in most patients and there are no other known long-term complications.

Nonglomerular Hematuria

Medical. Except for renal tumors, nonglomerular hematuria of renal origin is secondary to either tubulointerstitial, renovascular,

or systemic disorders. The urinalysis in nonglomerular hematuria is distinguished from that of glomerular hematuria by the presence of circular erythrocytes and the absence of erythrocyte casts. Like glomerular hematuria, nonglomerular hematuria of renal origin is frequently associated with significant proteinuria, which distinguishes these nephrologic diseases from urologic diseases in which the degree of proteinuria is usually minimal, even with heavy bleeding.

As with glomerular hematuria, a careful history frequently helps establish the diagnosis. A family history of hematuria or bleeding tendency suggests the diagnosis of a blood dyscrasia, which should be investigated further. A family history of urolithiasis associated with intermittent hematuria may indicate stone disease, which should be investigated with serum and urine measurements of calcium and uric acid. A family history of renal cystic disease should prompt further radiologic evaluation for medullary sponge kidney and adult polycystic kidney disease. Papillary necrosis as a cause of hematuria should be considered in diabetics, African-Americans (secondary to sickle cell disease or trait), and suspected analgesic abusers.

Medications may induce hematuria, particularly anticoagulants. Anticoagulation at normal therapeutic levels, however, does not predispose patients to hematuria. In one study, the prevalence of hematuria was 3.2% in anticoagulated patients versus 4.8% in a control group. Urologic disease was identified in 81% of patients with more than one episode of microscopic hematuria, and the cause of hematuria did not vary between groups (Culclasure et al, 1994). Thus anticoagulant therapy per se does not appear to increase the risk of hematuria unless the patient is excessively anticoagulated.

Exercise-induced hematuria is being observed with increasing frequency. It typically occurs in long-distance runners (>10 km), is usually noted at the conclusion of the run, and rapidly disappears with rest. The hematuria may be of renal or bladder origin. An increased number of dysmorphic erythrocytes have been noted in some patients, suggesting a glomerular origin. Exercise-induced hematuria may be the first sign of underlying glomerular disease such as IgA nephropathy. Conversely, cystoscopy in patients with

exercise-induced hematuria frequently reveals punctate hemorrhagic lesions in the bladder, suggesting that the hematuria is of bladder origin.

Vascular disease may also result in nonglomerular hematuria. Renal artery embolism and thrombosis, arteriovenous fistulae, and renal vein thrombosis may all result in hematuria. Physical examination may reveal severe hypertension, a flank or abdominal bruit, or atrial fibrillation. In such patients, further evaluation for renal vascular disease should be undertaken.

An algorithm for the evaluation of nonglomerular hematuria is provided in Figure 1-7.

Surgical. Nonglomerular hematuria or essential hematuria includes primarily urologic rather than nephrologic diseases. Common causes of essential hematuria include urologic tumors, stones, and UTIs.

The urinalysis in both nonglomerular medical and surgical hematuria is similar in that both are characterized by circular erythrocytes and the absence of erythrocyte casts. Essential hematuria is suggested, however, by the absence of significant proteinuria usually found in nonglomerular hematuria of renal parenchymal origin. It should be remembered, however, that proteinuria is not always present in glomerular or nonglomerular renal disease.

The AUA Best Practice Policy Panel on Microscopic Hematuria has formulated practice recommendations for the detection and evaluation of asymptomatic microscopic hematuria (Grossfeld et al, 2001a, 2001b). The panel concluded that, due to the lack of specificity of urinary dipstick examination, as well as the risk and expense of evaluation, patients with a positive dipstick test should only undergo complete evaluation for hematuria if this is confirmed by the finding of 3 or more RBCs/HPF on subsequent microscopic evaluation. The mainstays of evaluation, according to the panel, are voided urinary cytology, cystoscopy, and urinary tract imaging using ultrasonography, CT, and/or intravenous urography (IVU). The use of these tests in an individual patient should be based in most cases on the relative risk of significant urinary tract pathology.

An algorithm for the evaluation of essential hematuria is provided in Figure 1-8.

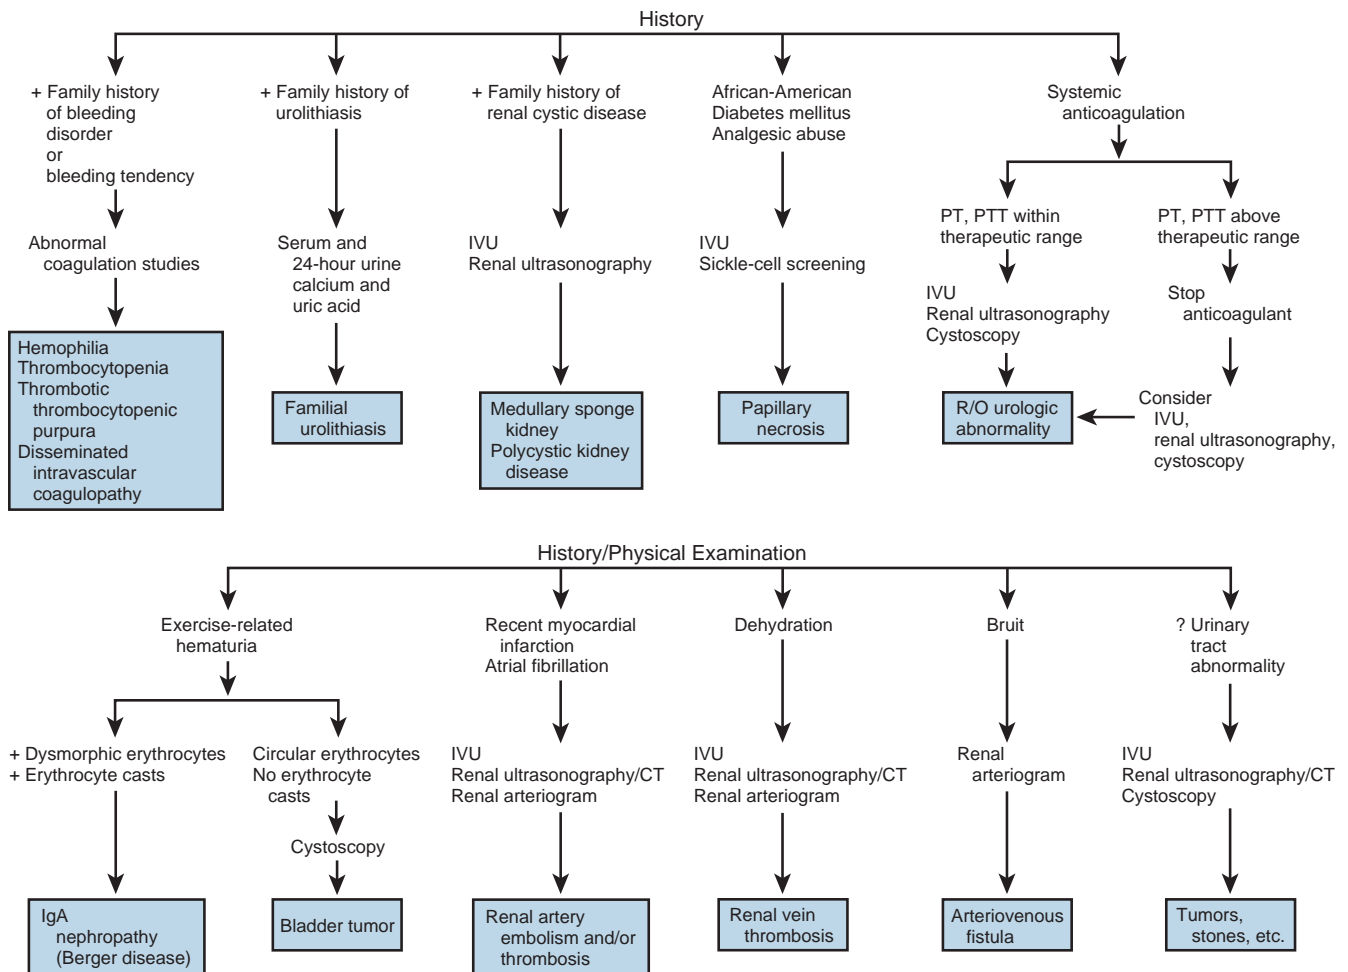

Figure 1-7. Evaluation of nonglomerular renal hematuria (circular erythrocytes, no erythrocyte casts, and proteinuria). CT, computed tomography; IgA, immunoglobulin A; IVU, intravenous urography; PT, prothrombin time; PTT, partial thromboplastin time; R/O, rule out.

Proteinuria

Although healthy adults excrete 80 to 150 mg of protein in the urine daily, the qualitative detection of proteinuria in the urinalysis should raise the suspicion of underlying renal disease. Proteinuria may be the first indication of renovascular, glomerular, or tubulointerstitial renal disease, or it may represent the overflow of abnormal proteins into the urine in conditions such as multiple myeloma. Proteinuria can also occur secondary to nonrenal disorders and in response to various physiologic conditions such as strenuous exercise.

The protein concentration in the urine depends on the state of hydration, but it seldom exceeds 20 mg/dL. In patients with dilute urine, however, significant proteinuria may be present at concentrations less than 20 mg/dL. Normally, urine protein is about 30% albumin, 30% serum globulins, and 40% tissue proteins, of which the major component is Tamm-Horsfall protein. This profile may be altered by conditions that affect glomerular filtration, tubular reabsorption, or excretion of urine protein. Determination of the urine protein profile by such techniques as protein electrophoresis may help determine the etiology of proteinuria.

Pathophysiology. Most causes of proteinuria can be categorized into one of three categories: glomerular, tubular, or overflow. Glomerular proteinuria is the most common type of proteinuria and results from increased glomerular capillary permeability to protein, especially albumin. Glomerular proteinuria occurs in any of the primary glomerular diseases such as IgA nephropathy or in glomerulopathy associated with systemic illness such as diabetes

mellitus. Glomerular disease should be suspected when the 24-hour urine protein excretion exceeds 1 g and is almost certain to exist when the total protein excretion exceeds 3 g.

Tubular proteinuria results from failure to reabsorb normally filtered proteins of low molecular weight such as immunoglobulins. In tubular proteinuria, the 24-hour urine protein loss seldom exceeds 2 to 3 g and the excreted proteins are of low molecular weight rather than albumin. Disorders that lead to tubular proteinuria are commonly associated with other defects of proximal tubular function such as glucosuria, aminoaciduria, phosphaturia, and uricosuria (Fanconi syndrome).

Overflow proteinuria occurs in the absence of any underlying renal disease and is due to an increased plasma concentration of abnormal immunoglobulins and other low-molecular-weight proteins. The increased serum levels of abnormal proteins result in excess glomerular filtration that exceeds tubular reabsorptive capacity. The most common cause of overflow proteinuria is multiple myeloma, in which large amounts of immunoglobulin light chains are produced and appear in the urine (Bence Jones protein).

Detection. Qualitative detection of abnormal proteinuria is most easily accomplished with a dipstick impregnated with tetrabromophenol blue dye. The color of the dye changes in response to a pH shift related to the protein content of the urine, mainly albumin, leading to the development of a blue color. Because the background of the dipstick is yellow, various shades of green will develop, and the darker the green, the greater the concentration of protein in the urine. The minimal detectable protein concentration by this method is 20 to 30 mg/dL. False-negative results can occur in alkaline

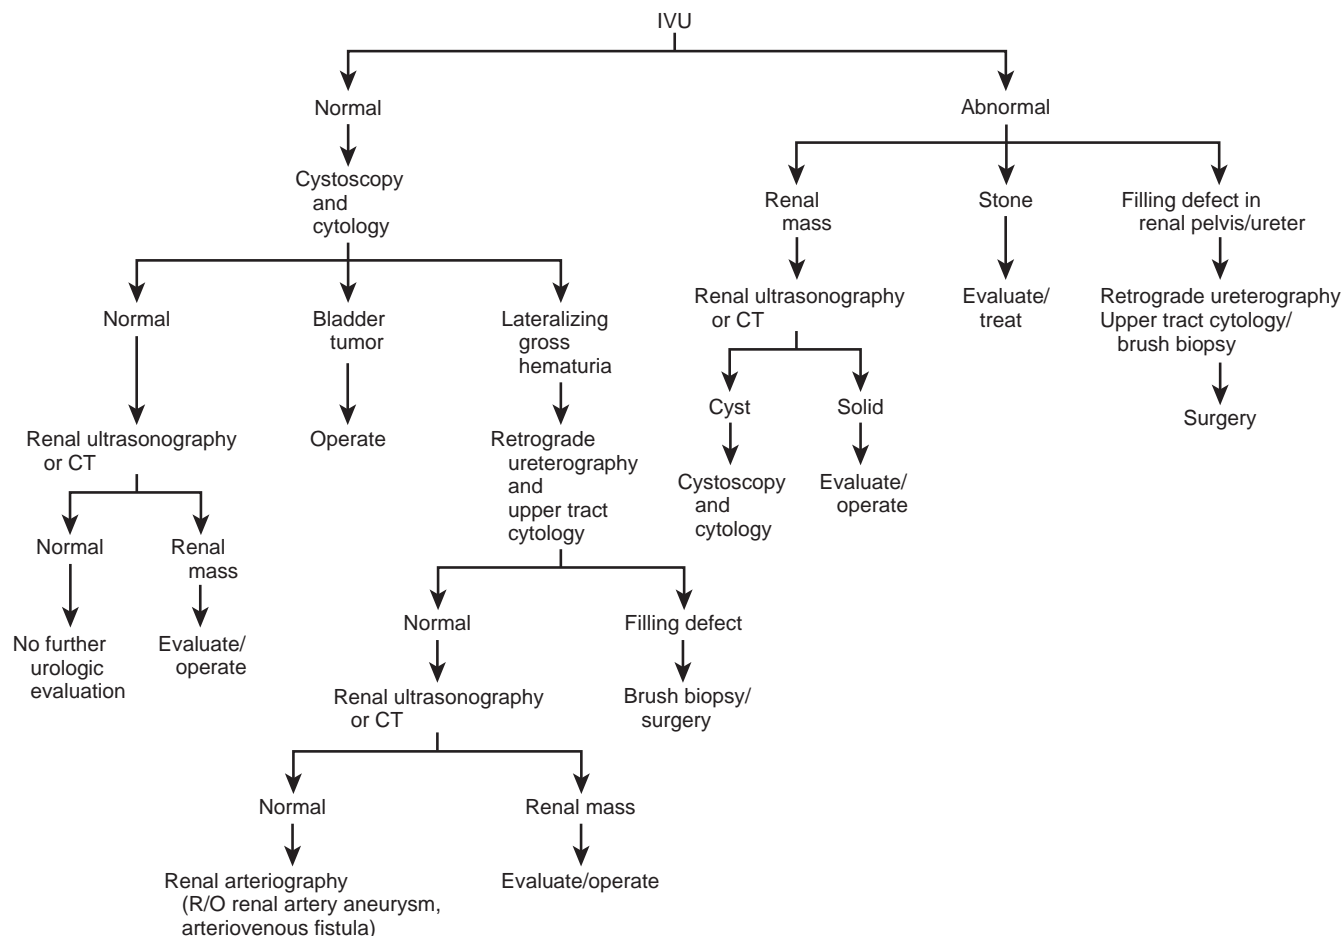

Figure 1-8. Evaluation of essential hematuria (circular erythrocytes, no erythrocyte casts, no significant proteinuria). CT, computed tomography; IVU, intravenous urography; R/O, rule out.

urine, dilute urine, or when the primary protein present is not albumin. Nephrotic range proteinuria in excess of 1 g/24 hr, however, is seldom missed on qualitative screening. Precipitation of urinary proteins with strong acids such as 3% sulfosalicylic acid will detect proteinuria at concentrations as low as 15 mg/dL and is more sensitive at detecting other proteins and albumin. Patients whose urine is negative on dipstick but strongly positive with sulfosalicylic acid should be suspected of having multiple myeloma, and the urine should be tested further for Bence Jones protein.

If qualitative testing reveals proteinuria, this should be titrated with a 24-hour urinary collection. Further qualitative assessment of abnormal urinary proteins can be accomplished by either protein electrophoresis or immunoassay for specific proteins. Protein electrophoresis is particularly helpful in distinguishing glomerular from tubular proteinuria. In glomerular proteinuria, albumin makes up about 70% of the total protein excreted, whereas in tubular proteinuria, the major proteins excreted are immunoglobulins with albumin making up only 10% to 20%. Immunoassay is the method of choice for detecting specific proteins such as Bence Jones protein in multiple myeloma.

Evaluation. Proteinuria should first be classified by its timing into transient, intermittent, or persistent. Transient proteinuria occurs commonly, especially in the pediatric population, and usually resolves spontaneously within a few days (Wagner et al, 1968). It may result from fever, exercise, or emotional stress. In older patients, transient proteinuria may be due to congestive heart failure. If a nonrenal cause is identified and a subsequent urinalysis is negative, no further evaluation is necessary. If proteinuria persists, it should be evaluated further.

Proteinuria may also occur intermittently, and this is frequently related to postural change (Robinson, 1985). Proteinuria

that occurs only in the upright position is a frequent cause of mild, intermittent proteinuria in young males. Total daily protein excretion seldom exceeds 1 g, and urinary protein excretion returns to normal when the patient is recumbent. Orthostatic proteinuria is thought to be secondary to increased pressure on the renal vein while standing. It resolves spontaneously in about 50% of patients and is not associated with any morbidity. Therefore if renal function is normal in patients with orthostatic proteinuria, no further evaluation is indicated.

Persistent proteinuria requires further evaluation, and most cases have a glomerular etiology. A quantitative measurement of urinary protein should be obtained through a 24-hour urine collection, and a qualitative evaluation should be obtained to determine the major proteins excreted. The findings of greater than 2 g of protein excreted per 24 hours, of which the major components are high-molecular-weight proteins such as albumin, establish the diagnosis of glomerular proteinuria. Glomerular proteinuria is the most common cause of abnormal proteinuria, especially in patients presenting with persistent proteinuria. If glomerular proteinuria is associated with hematuria characterized by dysmorphic erythrocytes and erythrocyte casts, the patient should be evaluated as outlined previously for glomerular hematuria (see Fig. 1-6). Patients with glomerular proteinuria who have no or little associated hematuria should be evaluated for other conditions, of which the most common is diabetes mellitus. Other possibilities include amyloidosis and arteriolar nephrosclerosis.

In patients in whom total protein excretion is 300 to 2000 mg/day, of which the major components are low-molecular-weight globulins, further qualitative evaluation with immunoelectrophoresis is indicated. This will determine whether the excess proteins are normal or abnormal. Identification of normal proteins

establishes a diagnosis of tubular proteinuria, and further evaluation for a specific cause of tubular dysfunction is indicated.

If qualitative evaluation reveals abnormal proteins in the urine, this establishes a diagnosis of overflow proteinuria. Further evaluation should be directed to identify the specific protein abnormality. The finding of large quantities of light-chain immunoglobulins or Bence Jones protein establishes a diagnosis of multiple myeloma. Similarly, the finding of large amounts of hemoglobin or myoglobin establishes the diagnosis of hemoglobinuria or myoglobinuria.

An algorithm for the evaluation of proteinuria is provided in Figure 1-9.

Glucose and Ketones

Urine testing for glucose and ketones is useful in screening patients for diabetes mellitus. Normally, almost all the glucose filtered by the glomeruli is reabsorbed in the proximal tubules. Although small amounts of glucose may normally be excreted in the urine, these amounts are not clinically significant and are below the level of detectability with the dipstick. If, however, the amount of glucose filtered exceeds the capacity of tubular reabsorption, glucose will be excreted in the urine and detected on the dipstick. This so-called renal threshold corresponds to serum glucose of about 180 mg/dL; above this level, glucose will be detected in the urine.

Glucose detection with the urinary dipstick is based on a double sequential enzymatic reaction yielding a colorimetric change. In the first reaction, glucose in the urine reacts with glucose oxidase on the dipstick to form gluconic acid and hydrogen peroxide. In the second reaction, hydrogen peroxide reacts with peroxidase, causing oxidation of the chromogen on the dipstick, producing a color change. This double-oxidative reaction is specific for glucose, and there is no cross-reactivity with other sugars. The dipstick test becomes less sensitive as the urine increases in specific gravity and temperature.

Ketones are not normally found in the urine but will appear when the carbohydrate supplies in the body are depleted and body fat breakdown occurs. This happens most commonly in diabetic ketoacidosis but may also occur during pregnancy and after periods of starvation or rapid weight reduction. Ketones excreted include acetoacetic acid, acetone, and β -hydroxybutyric acid. With abnormal fat breakdown, ketones will appear in the urine before the serum.

Dipstick testing for ketones involves a colorimetric reaction: Sodium nitroprusside on the dipstick reacts with acetoacetic acid to produce a purple color. Dipstick testing will identify acetoacetic acid at concentrations of 5 to 10 mg/dL but will not detect acetone or β -hydroxybutyric acid. A dipstick that tests positively for glucose should also be tested for ketones, and diabetes mellitus is suggested. False-positive results, however, can occur in acidic urine of high specific gravity, in abnormally colored urine, and in urine containing levodopa metabolites, 2-mercaptoethane sulfonate sodium, and other sulfhydryl-containing compounds (Csako, 1987).

Bilirubin and Urobilinogen

Normal urine contains no bilirubin and only small amounts of urobilinogen. There are two types of bilirubin: direct (conjugated) and indirect. Direct bilirubin is made in the hepatocyte, where bilirubin is conjugated with glucuronic acid. Conjugated bilirubin has a low molecular weight, is water soluble, and normally passes from the liver into the small intestine through the bile ducts, where it is converted to urobilinogen. Therefore conjugated bilirubin does not appear in the urine except in pathologic conditions in which there is intrinsic hepatic disease or obstruction of the bile ducts.

Indirect bilirubin is of high molecular weight and bound in the serum to albumin. It is water insoluble and therefore does not appear in the urine even in pathologic conditions.

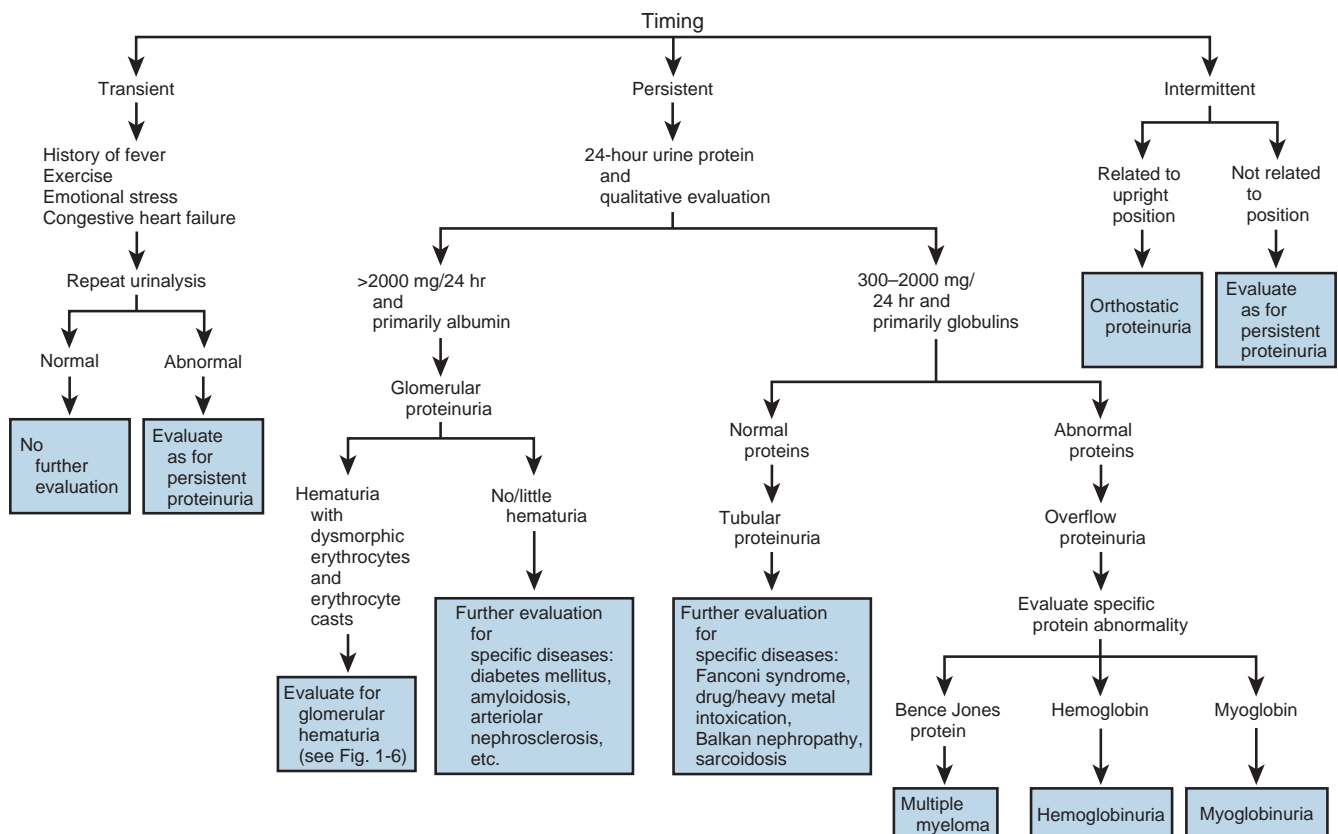

Figure 1-9. Evaluation of proteinuria.

Urobilinogen is the end product of conjugated bilirubin metabolism. Conjugated bilirubin passes through the bile ducts, where it is metabolized by normal intestinal bacteria to urobilinogen. Normally, about 50% of the urobilinogen is excreted in the stool and 50% is reabsorbed into the enterohepatic circulation. A small amount of absorbed urobilinogen, about 1 to 4 mg/day, will escape hepatic uptake and be excreted in the urine. Hemolysis and hepatocellular diseases that lead to increased bile pigments can result in increased urinary urobilinogen. Conversely, obstruction of the bile duct or antibiotic usage that alters intestinal flora, thereby interfering with the conversion of conjugated bilirubin to urobilinogen, will decrease urobilinogen levels in the urine. In these conditions, serum levels of conjugated bilirubin rise.

There are different dipstick reagents and methods to test for both bilirubin and urobilinogen, but the basic physiologic principle involves the binding of bilirubin or urobilinogen to a diazonium salt to produce a colorimetric reaction. False-negative results can occur in the presence of ascorbic acid, which decreases the sensitivity for detection of bilirubin. False-positive results can occur in the presence of phenazopyridine because it colors the urine orange and, similar to the colorimetric reaction for bilirubin, turns red in an acid medium.

Leukocyte Esterase and Nitrite Tests

Leukocyte esterase activity indicates the presence of white blood cells in the urine. The presence of nitrites in the urine is strongly suggestive of bacteriuria. Thus both of these tests have been used to screen patients for UTIs. Although these tests may have application in nonurologic medical practice, the most accurate method to diagnose infection is by microscopic examination of the urinary sediment to identify pyuria and subsequent urine culture. All urologists should be capable of performing and interpreting the microscopic examination of the urinary sediment. Therefore leukocyte esterase and nitrite testing are less important in a urologic practice. For purposes of completion, however, both techniques are described briefly herein.

Leukocyte esterase and nitrite testing are performed using the Chemstrip LN dipstick. Leukocyte esterase is produced by neutrophils and catalyzes the hydrolysis of an indoxyl carbonic acid ester to indoxyl (Gillenwater, 1981). The indoxyl formed oxidizes a diazonium salt chromogen on the dipstick to produce a color change. It is recommended that leukocyte esterase testing be done 5 minutes after the dipstick is immersed in the urine to allow adequate incubation (Shaw et al, 1985). The sensitivity of this test subsequently decreases with time because of lysis of the leukocytes. Leukocyte esterase testing may also be negative in the presence of infection because not all patients with bacteriuria will have significant pyuria. Therefore if one uses leukocyte esterase testing to screen patients for UTI, it should always be done in conjunction with nitrite testing for bacteriuria (Pels et al, 1989).

Other causes of false-negative results with leukocyte esterase testing include increased urinary specific gravity, glycosuria, presence of urobilinogen, medications that alter urine color, and ingestion of large amounts of ascorbic acid. The major cause of false-positive leukocyte esterase tests is specimen contamination.

Nitrites are not normally found in the urine, but many species of gram-negative bacteria can convert nitrates to nitrites. Nitrites can readily be detected in the urine because they react with the reagents on the dipstick and undergo diazotization to form a red azo dye. The specificity of the nitrite dipstick for detecting bacteriuria is higher than 90% (Pels et al, 1989). The sensitivity of the test, however, is considerably less, varying from 35% to 85%. The nitrite test is less accurate in urine specimens containing fewer than 10^5 organisms/mL (Kellogg et al, 1987). As with leukocyte esterase testing, the major cause of false-positive nitrite testing is contamination.

It remains controversial whether dipstick testing for leukocyte esterase and nitrites can replace microscopy in screening for significant UTIs. This issue is less important to urologists, who usually have access to a microscope and who should be trained and

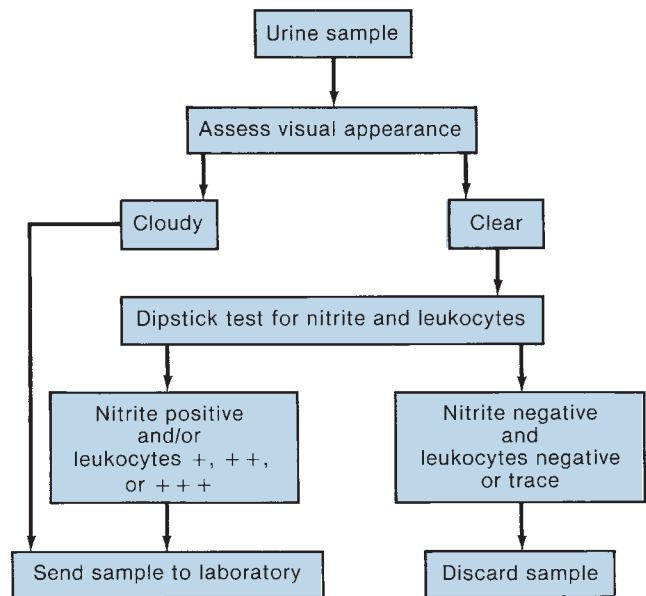

Figure 1-10. Protocol for determining the need for urine sediment microscopy in an asymptomatic population. (From Flanagan PG, Rooney PG, Davies EA, et al. Evaluation of four screening tests for bacteriuria in elderly people. *Lancet* 1989;1:1117. © by The Lancet Ltd., 1989.)

encouraged to examine the urinary sediment. A protocol combining the visual appearance of the urine with leukocyte esterase and nitrite testing has been proposed (Fig. 1-10). It reportedly detects 95% of infected urine specimens and decreases the need for microscopy by as much as 30% (Flanagan et al, 1989). Other studies, however, have shown that dipstick testing is not an adequate replacement for microscopy (Propp et al, 1989). In summary, it has not been demonstrated conclusively that dipstick testing for UTI can replace microscopic examination of the urinary sediment. In our personal experience, we always examine the urinary sediment whenever we suspect a UTI and subsequently culture the urine when pyuria is identified.

Urinary Sediment

Obtaining and Preparing the Specimen

A clean-catch midstream urine specimen should be obtained. As described earlier, uncircumcised men should retract the prepuce and cleanse the glans penis before voiding. It is more difficult to obtain a reliable clean-catch specimen in females because of contamination with introital leukocytes and bacteria. If there is any suspicion of a UTI in a female, a catheterized urine sample should be obtained for culture and sensitivity.

If possible, the first morning urine specimen is the specimen of choice and should be examined within 1 hour. A standard procedure for preparation of the urine for microscopic examination has been described (Cushner and Copley, 1989). Ten to 15 milliliters of urine should be centrifuged for 5 minutes at 3000 rpm. The supernatant is then poured off, and the sediment is resuspended in the centrifuge tube by gently tapping the bottom of the tube. Although the remaining small amount of fluid can be poured onto a microscope slide, this usually results in excess fluid on the slide. It is better to use a small pipette to withdraw the residual fluid from the centrifuge tube and to place it directly on the microscope slide. This usually results in an ideal volume of between 0.01 and 0.02 mL of fluid deposited on the slide. The slide is then covered with a coverslip. The edge of the coverslip should be placed on the slide first to allow the drop of fluid to ascend onto the coverslip by capillary action. The coverslip is then gently placed over the drop of fluid, and this technique allows for most of the air between the drop of

fluid and the coverslip to be expelled. If one simply drops the coverslip over the urine, the urine will disperse over the slide and there will be a considerable number of air bubbles that may distort the subsequent microscopic examination.

Microscopy Technique

Microscopic analysis of the urinary sediment should be performed with both low-power ($\times 100$ magnification) and high-power ($\times 400$ magnification) lenses. The use of an oil immersion lens for higher magnification is seldom, if ever, necessary. Under low power, the entire area under the coverslip should be scanned. **Particular attention should be given to the edges of the coverslip, where casts and other elements tend to be concentrated.** Low-power magnification is sufficient to identify erythrocytes, leukocytes, casts, cystine crystals, oval fat macrophages, and parasites such as *Trichomonas vaginalis* and *Schistosoma hematobium*.

High-power magnification is necessary to distinguish circular from dysmorphic erythrocytes, to identify other types of crystals, and, particularly, to identify bacteria and yeast. In summary, **the urinary sediment should be examined microscopically for (1) cells, (2) casts, (3) crystals, (4) bacteria, (5) yeast, and (6) parasites.**

Cells

Erythrocyte morphology may be determined under high-power magnification. Although phase contrast microscopy has been used for this purpose, circular (nonglomerular) erythrocytes can generally be distinguished from dysmorphic (glomerular) erythrocytes under routine brightfield high-power magnification (Figs. 1-11 to 1-15). This is assisted by adjusting the microscope condenser to

its lowest aperture, thus reducing the intensity of background light. This allows one to see fine detail not evident otherwise and also creates the effect of phase microscopy because cell membranes and other sedimentary components stand out against the darkened background.

Circular erythrocytes generally have an even distribution of hemoglobin with either a round or crenated contour, whereas dysmorphic erythrocytes are irregularly shaped with minimal hemoglobin and irregular distribution of cytoplasm. Automated techniques for performing microscopic analysis to distinguish the two types of erythrocytes have been investigated but have not yet been accepted into general urologic practice and are probably unnecessary. In one study using a standard Coulter counter, microscopic analysis was found to be 97% accurate in differentiating between the two types of erythrocytes (Sayer et al, 1990). **Erythrocytes may be confused with yeast or fat droplets (Fig. 1-16).** Erythrocytes can be distinguished, however, because yeast will show budding and oil droplets are highly refractile.

Leukocytes can generally be identified under low power and definitively diagnosed under high-power magnification (Figs. 1-17 and 1-18; see also Fig. 1-16). It is normal to find 1 or 2 leukocytes/HPF in men and up to 5/HPF in women in whom the urine sample may be contaminated with vaginal secretions. A greater number of leukocytes generally indicates infection or inflammation in the urinary tract. It may be possible to distinguish **old leukocytes, which have a characteristic small and wrinkled appearance** and which are commonly found in the vaginal secretions of normal women, from fresh leukocytes, which are generally indicative of urinary tract pathology. Fresh leukocytes are generally larger and

Figure 1-19. Transitional epithelial cells from bladder lavage.

rounder, and, when the specific gravity is less than 1.019, the granules in the cytoplasm demonstrate glitterlike movement, so-called glitter cells.

Epithelial cells are commonly observed in the urinary sediment. Squamous cells are frequently detected in female urine specimens and are derived from the lower portion of the urethra, the trigone of postpubertal females, and the vagina. Squamous epithelial cells are large, have a central small nucleus about the size of an erythrocyte, and have an irregular cytoplasm with fine granularity.

Transitional epithelial cells may arise from the remainder of the urinary tract (Fig. 1-19). Transitional cells are smaller than squamous cells, have a larger nucleus, and demonstrate prominent cytoplasmic granules near the nucleus. Malignant transitional cells have altered nuclear size and morphology and can be identified with either routine Papanicolaou staining or automated flow cytometry.

Renal tubular cells are the least commonly observed epithelial cells in the urine but are most significant because their presence in the urine is always indicative of renal pathology. Renal tubular

Figure 1-20. Red blood cell cast. A, Low-power view demonstrates distinct border of hyaline matrix. B, High-power view demonstrates the sharply defined red blood cell membranes (arrow). Berger disease.

cells may be difficult to distinguish from leukocytes, but they are slightly larger.

Casts

A cast is a protein coagulum that is formed in the renal tubule and traps any tubular luminal contents within the matrix. **Tamm-Horsfall mucoprotein is the basic matrix of all renal casts; it originates from tubular epithelial cells and is always present in the urine.** When the casts contain only mucoproteins, they are called *hyaline casts* and may not have any pathologic significance. Hyaline casts may be seen in the urine after exercise or heat exposure but may also be observed in pyelonephritis or chronic renal disease.

RBC casts contain entrapped erythrocytes and are diagnostic of glomerular bleeding, most likely secondary to glomerulonephritis (Figs. 1-20 and 1-21). White blood cell casts are observed in acute glomerulonephritis, acute pyelonephritis, and acute tubulointerstitial nephritis. Casts with other cellular elements, usually sloughed renal tubular epithelial cells, are indicative of nonspecific renal damage (Fig. 1-22). Granular and waxy casts result from further degeneration of cellular elements. Fatty casts are seen in nephrotic syndrome, lipiduria, and hypothyroidism.

Crystals

Identification of crystals in the urine is particularly important in patients with stone disease because it may help determine the etiology (Fig. 1-23). Although other types of crystals may be seen in normal patients, **the identification of cystine crystals establishes the diagnosis of cystinuria.** Crystals precipitated in acidic urine include calcium oxalate, uric acid, and cystine. Crystals precipitated in an alkaline urine include calcium phosphate and triple-phosphate (struvite) crystals. Cholesterol crystals are rarely seen in the urine and are not related to urinary pH. They occur in lipiduria and remain in droplet form.

Bacteria

Normal urine should not contain bacteria; in a fresh uncontaminated specimen, the finding of bacteria is indicative of a UTI. Because each HPF views between 1/20,000 and 1/50,000 mL, each bacterium seen per HPF signifies a bacterial count of more than 30,000/mL. Therefore, **5 bacteria/HPF reflects colony counts of about 100,000/mL.** This is the standard concentration used to establish the diagnosis of a UTI in a clean-catch specimen. This level should apply only to women, however, in whom a clean-catch specimen is frequently contaminated. The finding of any bacteria in a properly collected midstream specimen from a male should be further evaluated with a urine culture.

Figure 1-21. Red blood cell cast.

Figure 1-22. Cellular cast. Cells entrapped in a hyaline matrix.

Under high power, it is possible to distinguish various bacteria. Gram-negative rods have a characteristic bacillary shape (Fig. 1-24), whereas streptococci can be identified by their characteristic beaded chains (Figs. 1-25 and 1-26) and staphylococci can be identified when the organisms are found in clumps (Fig. 1-27).

Yeast

The most common yeast cells found in urine are *Candida albicans*. The biconcave oval shape of yeast can be confused with

Crystals

erythrocytes and calcium oxalate crystals, but yeasts can be distinguished by their characteristic budding and hyphae (see Fig. 1-16). Yeasts are most commonly seen in the urine of patients with diabetes mellitus or as contaminants in women with vaginal candidiasis.

Parasites

Trichomonas vaginalis is a frequent cause of vaginitis in women and occasionally of urethritis in men. Trichomonads can be readily identified in a clean-catch specimen under low power (Fig. 1-28). Trichomonads are large cells with rapidly moving flagella that quickly propel the organism across the microscopic field.

Figure 1-29. Oval fat macrophage. A, High-power view showing doubly refractile fat particles (arrow). B, Phase microscopy of the same specimen (arrow).

Schistosoma hematobium is a urinary tract pathogen that is not found in the United States but is extremely common in countries of the Middle East and North Africa. Examination of the urine shows the characteristic parasitic ova with a terminal spike.

Expressed Prostatic Secretions

Although not strictly a component of the urinary sediment, the expressed prostatic secretions should be examined in any man suspected of having prostatitis. Normal prostatic fluid should contain few, if any, leukocytes, and the presence of a larger number or clumps of leukocytes is indicative of prostatitis. **Oval fat macrophages are found in postinfection prostatic fluid (Figs. 1-29 and 1-30).** Normal prostatic fluid contains numerous secretory granules that resemble but can be distinguished from leukocytes under high power because they do not have nuclei.

Figure 1-30. Oval fat macrophage, high-power view. Note the fine secretory granules in the prostatic fluid.

SUMMARY

This chapter has detailed the basic evaluation of the urologic patient, which should include a careful history, physical examination, and urinalysis. These three basic components form the cornerstone of the urologic evaluation and should precede any subsequent diagnostic procedures. After completion of the history, physical examination, and urinalysis, the urologist should be able to establish at least a differential, if not specific, diagnosis that will allow the subsequent diagnostic evaluation and treatment to be carried out in a direct and efficient manner.

Nuclear Scintigraphy

Computed Tomography

Magnetic Resonance Imaging

Imaging continues to play an indispensable role in the diagnosis and management of urologic diseases. Because many urologic conditions cannot be assessed by physical examination, conventional radiography has long been critical to the diagnosis of conditions of the adrenals, kidneys, ureters, and bladder. The development of computed tomography (CT) imaging and the use of intravenous contrast agents have provided detailed anatomic, functional, and physiologic information about urologic conditions. In this chapter we will discuss the indications for imaging in urology with an emphasis on the underlying physical principles of the imaging modalities. The strengths and limitations of each modality, as well as the techniques necessary to maximize image quality and minimize the risks and harms to urologic patients, are discussed.

CONVENTIONAL RADIOGRAPHY

Conventional radiography, although eclipsed by CT and magnetic resonance imaging (MRI) for certain indications, remains useful for preoperative diagnosis and postoperative evaluation in a variety of different urologic conditions. Conventional radiography includes abdominal plain radiography, intravenous excretory urography, retrograde pyelography, loopography, retrograde urethrography, and cystography. Urologists frequently perform and interpret conventional radiography examinations, including fluoroscopic examinations, in the office and operating room environments.

Physics

It is important for urologists to understand the physics of conventional radiography and fluoroscopy, as well as the implications and dangers of radiation exposure to the patient and the operator. The underlying physical principles of conventional radiography involve emitting a stream of photons from an x-ray source. These photons travel through the air and strike tissue, imparting energy to that tissue. Some of the photons emerge from the patient with varying amounts of energy attenuation and strike an image recorder such as a film cassette or the input phosphor of an image-intensifier tube, thus producing an image (Fig. 2-1).

RADIATION MANAGEMENT IN URORADIOLOGY

When diagnostic radiation passes through tissue, it creates ion pairs. The resultant charge per unit mass of air is referred to as the **radiation exposure**. The current unit of radiation exposure is coulombs(C)/kg. **Absorbed dose** is the energy absorbed from the radiation exposure and is measured in units called gray (Gy). The older unit of absorbed dose was called the rad (1 rad =100 Gy).

Because different types of radiation have different types of interaction with tissue, a conversion factor is applied to better express the amount of energy absorbed by a given tissue. The application of this conversion factor to the **absorbed dose** yields the **equivalent dose** measured in sieverts (Sv). For diagnostic x-rays the conversion factor is 1, so the absorbed dose is the same as the equivalent dose. When discussing the amount of radiation energy absorbed by patients during therapeutic radiation, the dose is given in gray. When discussing exposure to patients or medical personnel because of diagnostic ionizing radiation procedures, the dose is given in sieverts.

The distribution of energy absorption in the human body will be different based on the body part being imaged and a variety of other factors. The most important risk of radiation exposure from diagnostic imaging is the development of cancer. The **effective dose** is a quantity used to denote the radiation risk (expressed in **sieverts**) to a population of patients from an imaging study. See Table 2-1 for a description of the relationship between these measures of radiation exposure.

The average person living in the United States is exposed to 6.2 mSv of radiation per year from ambient sources, such as radon and cosmic rays, and medical procedures, which account for 36% of the annual radiation exposure (National Council on Radiation Protection and Measurements, 2012). The recommended occupational exposure limit to medical personnel is 50 mSv per year (National Council on Radiation Protection and Measurements, 2012). Exposure to the eyes and gonads has a more significant biologic impact than exposure to the extremities, so recommended exposure limits vary according to the body part. The linear no-threshold model (LNT) used in radiation protection to quantify exposition and to set regulatory limits assumes that the long-term, biologic damage caused by ionizing radiation is directly

proportional to the dose. **Based on the LNT, there is no safe dose of radiation.** An effective radiation dose of as little as 10 mSv may result in the development of a malignancy in 1 of 1000 individuals exposed (National Research Council of the National Academies, 2006).

Relative Radiation Levels

The assessment of biologic risk from radiation exposure is complex. By estimating the range of effective doses for various imaging modalities, they can be assigned a **relative radiation level (RRL)** (Table 2-2). The effective dose from a 3-phase CT of the abdomen and pelvis without and with contrast may be as high as 25 to 40 mSv. Another often overlooked source of significant radiation exposure is fluoroscopy. Fluoroscopy for 1 minute results in a radiation dose to the skin equivalent to 10 times that of a single radiograph of the same anatomic area (Geise and Morin, 2000).

Radiation Protection

The cumulative dose of radiation to patients increases relatively rapidly with repeated CT imaging studies or procedures guided by fluoroscopy. Certain patient populations such as those with recurrent renal calculus disease or those with a urologic malignancy may be at increased risk of developing cancer because of repeated exposures to ionizing radiation. Attempts should be made to limit axial imaging studies to the anatomic area of interest and to substitute imaging studies not requiring ionizing radiation when feasible. The cumulative dose of radiation to medical personnel, including physicians, may increase relatively rapidly when fluoroscopy is used.

Figure 2-1. Equipment setup for fluoroscopy. The x-ray source located beneath the table reduces the radiation exposure to the surgeon. Locating the image intensifier as close to the patient as feasible reduces scatter radiation. Equipment setup will vary based on application.

Reduction in radiation exposure to medical personnel is achieved by three major mechanisms: (1) limiting the time of exposure; (2) maximizing distance from the radiation source; and (3) shielding. Radiation dose during fluoroscopy is directly proportional to the **time of exposure** and the **number of exposures**. The exposure time during fluoroscopy should be minimized by using short bursts of fluoroscopy and using the “last image hold” feature of the fluoroscopy unit. Radiation beams diverge with distance, and therefore radiation exposure diminishes as the square of the distance from the radiation source. Maintaining the maximum practical distance from an active radiation source significantly decreases exposure to medical personnel. Positioning the image intensifier as close as feasible to the patient substantially reduces scatter radiation. Standard aprons, thyroid shields, proper eye protection, and leaded gloves provide significant shielding for medical personnel and should be worn by all personnel involved in the use of fluoroscopy. **A practice of routinely collimating to the minimum required visual fluoroscopy field results in significant reductions in radiation exposure, compared with a usual approach to collimation. This may have important implications for decreasing the risk of malignancy in patients and operators.**

KEY POINTS: CONVENTIONAL RADIOGRAPHY/ RADIATION MANAGEMENT IN UROLOGY

- The effective radiation dose describes the potential for adverse health effects from ionizing radiation.
- The effective dose is a quantity used to denote the radiation risk (expressed in sieverts) to a population of patients from an imaging study. See Table 2-1 for a description of the relationship between these measures of radiation exposure.
- Based on the LNT model, there is no safe dose of radiation.
- Relative radiation levels (RRL) categorize diagnostic imaging studies by their estimated effective dose of radiation.
- Radiation protection for medical personnel includes (1) limiting time of exposure; (2) maximizing distance from radiation source; and (3) shielding.
- Collimating to the minimum required visual fluoroscopy field reduces exposure to the patient and operator.

CONTRAST MEDIA

The urologist ordering a radiographic evaluation on a patient must consider the risks and benefits associated with a contrast-enhanced imaging study, as well as alternative imaging modalities that could provide the same information without the need for contrast exposure.

Many different types of contrast media have been used to enhance medical imaging and thus improve diagnostic and therapeutic decisions made by urologists. These agents are used on a daily basis throughout the world with great safety and efficacy. However, there are inherent risks associated with the use of contrast

TABLE 2-1 Units of Radiation Exposure and Clinical Relevance of the Measures

RADIATION QUANTITY	TRADITIONAL UNIT	SI UNIT	CONVERSION	CLINICAL RELEVANCE
Exposure	Roentgen (R)	Coulomb (C)/kg	1 C/kg = 3876 R	Charge per unit mass
Absorbed dose	Rad	Gray (Gy)	1 Gy = 100 rad	Energy absorbed by tissue
Equivalent dose	Rem	Sievert (Sv)	1 Sv = 100 rem	Absorbed energy based on tissue type
Effective dose	Rem	Sievert (Sv)		Biologic risk associated with absorbed energy

TABLE 2-2 Radiation Exposure from Common Urologic Imaging Procedures

RELATIVE RADIATION LEVEL (RRL)	EFFECTIVE DOSE ESTIMATED RANGE	EXAMPLE EXAMINATIONS
None	0	Ultrasonography, MRI
Minimal	<0.1 mSv	Chest radiographs
Low	0.1-1.0 mSv	Lumbar spine radiographs, pelvic radiographs
Medium	1-10 mSv	Abdomen CT without contrast, nuclear medicine, bone scan, ^{99m} Tc-DMSA renal scan, IVP, retrograde pyelograms, KUB, CT chest with contrast
High	10 mSv-100 mSv	Abdomen CT without and with contrast, whole-body PET

CT, computed tomography; IVP, intravenous pyelogram; KUB, kidneys, ureters, bladder; MRI, magnetic resonance imaging; ^{99m}Tc-DMSA, technetium 99m-dimercaptosuccinic acid; PET, positron emission tomography. Modified from American College of Radiology. ACR appropriateness criteria radiation dose assessment introduction, <http://www.acr.org/SecondaryMainMenuCategories/quality_safety/app_criteria/RRLInformation.aspx>; 2008.

media, as with other pharmaceuticals. Adverse side effects and adverse drug reactions (ADRs) can directly result from the use of contrast media and vary from minor disturbances to severe, life-threatening situations. Imaging centers must be prepared with trained personnel, readily available medications, equipment, and an ongoing system to educate clinic personnel on the recognition and treatment of ADRs associated with contrast media.

Intravascular Iodinated Contrast Media

Iodine is the most common element in general use as an intravascular radiologic contrast medium (IRCM). With an atomic weight of 127, iodine has radiopacity, whereas other elements included in IRCM have no radiopacity and act only as carriers of the iodine elements, increasing solubility, and reducing toxicity. Four basic types of iodinated IRCM are available for clinical use: ionic monomer, nonionic monomer, ionic dimer, and nonionic dimer. They can be further characterized as being iso-, hyper-, or low-osmolar compared to physiologic osmolality of 300 mOsm/kg water.

All are derived from a 2,4,6 tri-iodinated benzene ring compound with three atoms of iodine in the case of monomers and six atoms of iodine in the case of dimers. The chemical composition of these agents makes them highly hydrophilic, low in lipid solubility, and of low binding affinity for protein receptors or membranes. Because they do not enter red blood cells or tissue cells and are rapidly excreted, they are designed for use in imaging and are not therapeutic. Approximately 90% will be eliminated by the kidneys within 12 hours of administration.

Relative to the body's iodine stores, large quantities of iodine are required for imaging enhancement. The total body iodine content, found mainly in the thyroid gland is 0.01 g and the average daily turnover of iodine is only 0.0001 g. For renal CT imaging a common dose of IRCM will expose the patient to between 25 and 50 g of iodine, which is approximately 400,000 times the daily turnover rate in the human body, but this dose will rarely cause any toxicity or lasting effects (Morris, 1993).

Adverse Reactions to Intravascular Iodinated Contrast Media

ADRs associated with intravenous (IV) contrast media can be divided into two broad categories: idiosyncratic anaphylactoid (IA) and nonidiosyncratic (NI) reactions. The IA reactions are most concerning because they are potentially fatal and can occur without any predictable or predisposing factors. Approximately 85% of IA reactions occur during or immediately after injection of IRCM and are more common in patients who have a prior ADR to contrast media, have impaired renal function or diminished cardiac function, are on β -adrenergic blockers, or have asthma or diabetes (Spring et al, 1997).

The exact mechanism of IA reactions is unknown but thought to be a combination of systemic effects. IA reactions have not been shown to result from a true immunoglobulin E (IgE) antibody immunologic reaction to the contrast media (Dawson et al, 1999). At least four mechanisms may play a role in IA reactions: (1) release of vasoactive substances including histamine, (2) activation of physiologic cascades including complement, kinin, coagulation, and fibrinolytic systems, (3) inhibition of enzymes including cholinesterase, which may cause prolonged vagal stimulation, (4) the patient's own anxiety and fear of the actual procedure. IA reactions are not dose dependent. Severe reactions have been reported after an injection of only 1 mL at the beginning of a procedure and have also occurred after completion of a full dose despite no reaction to the initial test dose (Nelson et al, 1988; Thomsen et al, 1999; American College of Radiology, 2013).

NI reactions are dose dependent and consequently related to the osmolality, concentration, volume, and injection rate of the IRCM. Because the concentration of absorbed or free iodine is very low, only patients with an underlying iodine deficiency are at risk for increased intake of iodine during contrast imaging. Patients with endemic goiter may develop thyrotoxicosis after injection of IRCM agents.

The hyperosmolar contrast media (HOCM) have an osmolality that is five times greater than physiologic osmolality of body cells (300 mOsm/kg water). The hyperosmolar agents are associated with erythrocyte damage, endothelial damage, vasodilation, hypervolemia, interruption of the blood-brain barrier, and cardiac depression. Chemotoxic reactions to IRCM include cardiac, vascular, neurologic, and renal toxicity. The low osmolar contrast media (LOCM) have an osmolality the same as or slightly higher than physiologic osmolality and are associated with fewer ADRs and toxic events (Dawson et al, 1999).

Contrast Complications

The American College of Radiology (ACR) has divided these NI reactions to contrast agents into the following categories (American College of Radiology, 2013):

Mild Nonidiosyncratic Reactions

Fortunately, most NI reactions are classified as mild. Signs and symptoms appear self-limited without evidence of progression. These include the following:

Nausea, vomiting	Flushing
Cough	Chills, shaking
Warmth (heat)	Sweats
Headache	Rash, hives
Dizziness	Nasal stuffiness
Altered taste	Swelling: eyes, face
Itching	Anxiety
Pallor	

Treatment. Treatment consists of observation and reassurance; usually no intervention or medication is required. If needed, an H₁ receptor blocker such as diphenhydramine (Benadryl) orally (PO), intramuscularly (IM), or IV 1 to 2 mg/kg (up to 50 mg) may

be helpful. Be careful because these reactions may progress into a more severe category. If necessary, administer chlorphenamine, 4 to 10 mg PO/IM/IV, or diazepam 5 mg for anxiety.

Moderate Nonidiosyncratic Reactions

The following reactions occur in 0.5% to 2% of patients and require treatment but are not immediately life threatening.

Tachycardia/bradycardia	Dyspnea
Hypertension	Pronounced skin reaction
Pulmonary edema	Bronchospasm, wheezing
Hypotension	Laryngeal edema

Treatment. These reactions are usually transient and will need treatment with close observation. Appropriate treatments are hydrocortisone 100 to 500 mg IM or IV, or β -agonist inhalation for bronchospasm in addition to bronchiolar dilators (metaproterenol [Alupent], terbutaline [Brethaire], or albuterol [Proventil or Ventolin]) 2 to 3 puffs; repeat as necessary.

Severe Nonidiosyncratic Reactions

Life-threatening reactions occur in approximately 1 in 1000 uses for high osmolar agents and are far less frequent for low osmolar contrast media, with both types of agents resulting in mortality rates of 1 in 170,000 uses (Spring et al, 1997). Life-threatening events with more severe signs or symptoms include the following:

Laryngeal edema (severe or progressive)	Hypotension
Unresponsiveness	Convulsions
Cardiopulmonary arrest	Clinically manifest arrhythmias

Treatment. Immediate treatment is required. The patient will usually require emergency care involving particular attention to the respiratory and cardiovascular systems. If bronchospasm is severe and not responsive to inhalers, or if an upper airway edema (including laryngospasm) is present, epinephrine should be used promptly. Rapid administration of epinephrine is the treatment of choice for severe contrast reactions. Epinephrine can be administered in the dose of 0.01 mg/kg of 1:10,000 dilution or 0.1 mL/kg slowly into a running IV infusion of saline and can be repeated every 5 to 15 minutes as needed. If no IV access is available, the recommended IM dose of epinephrine is 0.01 mg/kg of 1:1000 dilution (or 0.01 mL/kg to a maximum of 0.15 mg of 1:1000 if less than 30 kg; 0.3 mg if weight is more than 30 kg) injected in the lateral thigh. Subcutaneous injection is much less effective (Lightfoot et al, 2009; American College of Radiology, 2013). Epinephrine must be administered with care to patients who have cardiac disease or those who are taking β -blockers because the unopposed alpha effects of epinephrine in these patients may cause severe hypertension or angina.

Antihistamines do not have a major role in the treatment of severe reactions. Careful monitoring of patient vital signs is paramount; the presence of both hypotension and tachycardia indicates a higher likelihood of anaphylactic reaction. Bradycardia is a sign of vasovagal reaction, and therefore the use of β -blockers is to be avoided. Hypotension resulting from an anaphylactic reaction can be treated with IV iso-osmolar fluids (e.g., 0.9% normal saline or Ringer lactate solution); several liters of fluid may be needed before obtaining a significant hemodynamic response. If fluid and oxygen are unsuccessful in reversing the patient's hypotension, the use of vasopressors is indicated. The most effective vasopressor is dopamine. Dopamine should be used at infusion rates between 2 and 10 μ g/kg/min.

Premedication Strategies

There is no known premedication strategy that will eliminate the risk of a severe adverse reaction to IRCM. The regimens suggested in the literature include the use of corticosteroids, antihistamines, H_1 and H_2 antagonists, and ephedrine. Patients at high risk should be premedicated with corticosteroids and possibly antihistamines 12 to 24 hours before and after use of IRCM. LOCM should be used in these patients. Several premedication regimens have been proposed to reduce the frequency and/or severity of reactions to contrast media. Two frequently used regimens are outlined in Box 2-1.

It has been demonstrated that the use of nonionic contrast media combined with a premedication strategy including corticosteroids results in a reduction in reaction rates compared to other protocols for patients who have experienced a prior contrast media-induced reaction. However, no controlled studies are available to determine whether pretreatment alters the incidence of serious reactions. Oral administration of steroids seems preferable to intravascular administration, and prednisone and methylprednisolone are equally effective. If the patient is unable to take oral medication, 200 mg of hydrocortisone IV may be substituted for oral prednisone. One consistent finding is that steroids should be given at least 6 hours before the injection of contrast media regardless of the route of steroid administration. It is clear that administration for 3 hours or less before contrast does not decrease adverse reactions (Lasser, 1988).

Supplemental administration of an H_1 antihistamine (e.g., diphenhydramine), PO or IV, may reduce the frequency of urticaria, angioedema, and respiratory symptoms. In emergency situations, IV corticosteroid (e.g., 200 mg hydrocortisone) every 4 hours plus an H_1 antihistamine (e.g., 50 mg diphenhydramine) 1 hour before the procedure has been used. In patients who have a prior, documented contrast reaction, the use of a different contrast agent has been advocated and may be protective. Switching to a different agent should be in combination with a premedication regimen.

Although rare, ADRs are reported after extravascular instillation of IRCM (e.g., retrograde pyelography). In patients with a positive history of previous severe IA or IN reactions to IRCM undergoing a nonvascular study, premedication with corticosteroids should be considered.

Delayed Contrast Reactions

Delayed contrast reactions can occur from 3 hours to 7 days following the administration of contrast. These reactions are identified in as many as 14% to 30% of patients after the injection of ionic monomers and in 8% to 10% of patients after the injection of nonionic monomers. Cutaneous reactions are the most frequent

BOX 2-1 Premedication Strategies to Reduce Severity of Reactions to Contrast Media

1. Prednisone—50 mg PO at 13 hr, 7 hr, and 1 hr before contrast media injection
Plus diphenhydramine (Benadryl)—50 mg IV, IM, or PO 1 hr before contrast medium injection
2. Methylprednisolone (Medrol)—32 mg PO 12 hr and 2 hr before contrast media injection
Plus diphenhydramine (Benadryl)—50 mg IV, IM, or PO 1 hr before contrast medium injection

From ACR Committee on Drugs and Contrast Media. ACR manual on contrast media: version 9, <<http://www.acr.org/quality-safety/resources/-/media/37D84428BF1D4E1B9A3A2918DA9E27A3.pdf>>; 2013 [accessed 06.10.14].

form of delayed contrast reaction with a reported incidence of 0.5% to 9%. The most common reactions include a cutaneous exanthem or pruritus without urticaria. Nausea, vomiting, drowsiness, headache and flulike symptoms can also occur. These signs and symptoms almost always resolve spontaneously.

Specific Contrast Consideration

Cardiac Abnormalities. Patients with underlying cardiac disease, including chest pain and cardiac arrest, have an increased incidence and/or severity of cardiovascular side effects. Pulmonary angiography and intracardiac and coronary artery injections carry the highest degree of risk. Possible reactions include hypotension, tachycardia, and arrhythmias. More severe but uncommon reactions include congestive heart failure, pulmonary edema, and cardiac arrest.

Extravasation of Contrast Material. Large-volume extravasation can be seen with power injections not monitored with electrical skin impedance devices that detect extravasation and arrest the injection process. When large-volume extravasation of IRCM occurs, the result can be swelling, edema, erythema, pain, and cellulitis. The most severe consequences may not be manifest immediately, and the inflammatory reaction usually reaches a maximum in 24 to 48 hours. The primary underlying mechanism is believed to be the hyperosmolality of the contrast agent. Mechanical compression caused by a compartment syndrome may also occur, leading to tissue necrosis. Management steps are immediate cessation of injection, notification of responsible and referring physicians, and elevation of the affected extremity above the level of the heart. If a large volume of extravasate occurs, manual massage is recommended to promote drainage. If the patient becomes symptomatic, plastic surgery consultation may also be needed. Admission to the hospital for observation or frequent follow-up in clinic may be necessary in some cases of large-volume extravasation.

Metformin. Metformin, an oral antihyperglycemic drug used to treat diabetes, is eliminated unchanged through the kidneys, most likely by glomerular filtration and tubular excretion. As a biguanide, it stimulates intestinal production of lactic acid. Some conditions can reduce metformin excretion or increase serum lactate, such as renal disease (decreases metformin excretion), liver disease (decreases lactic acid metabolism), and cardiac disease (increases anaerobic metabolism). Patients with type 2 diabetes mellitus receiving metformin may have an accumulation of the drug after administering IRCM, resulting in biguanide lactic acidosis with symptoms of vomiting, diarrhea, and somnolence. This condition is fatal in approximately 50% of cases (Wiholm and Myrhed, 1993). Biguanide lactic acidosis is rare in patients with normal renal function. Consequently in patients with normal renal function and no known comorbidities there is no need to discontinue metformin before IRCM use, nor is there a need to check creatinine following the imaging study. However, in patients with renal insufficiency metformin should be discontinued the day of the study and withheld for 48 hours. Postprocedure creatinine should be measured at 48 hours and metformin started once kidney function is normal (Bailey and Turner, 1996). It is not necessary to discontinue metformin before gadolinium-enhanced MRI studies when the amount of gadolinium administered is in the usual dosage range of 0.1 to 0.3 mmol per kilogram of body weight.

Contrast-Induced Nephropathy. While there are no standard criteria for contrast-induced nephropathy (CIN), the diagnosis can be made if one of the following occurs within 48 hours after administration of iodinated contrast medium: increase in serum creatinine of greater than 0.3 mg/dL, more than a 50% increase in serum creatinine from baseline, or urine output reduced to less than 0.5 mL/kg/hr for at least 6 hours (Mehta et al, 2007). The precise cause of CIN is still unknown but is believed to be a combination of tubular toxicity, tubular obstruction, and renal ischemia by vasoconstriction (Katholi et al, 1998; Heinrich et al, 2005). High doses of IRCM can impair renal function in some patients for 3 to 5 days, and the creatinine level usually returns to baseline in 10 to 14 days.

The incidence of contrast agent-related nephropathy is estimated to be 2% to 5%, and up to 25% of those with CIN will have persistent renal dysfunction. Clinical manifestations are highly variable and may be absent or proceed to oliguria. CIN in patients with normal kidney function is rare (Pannu et al, 2006; Kelly et al, 2008). CIN is the third most common cause of acute kidney failure in hospitalized patients (Nash et al, 2002).

The most common patient-related risk factors for CIN are chronic kidney disease (creatinine clearance <60 mL/min), diabetes mellitus, dehydration, diuretic use, advanced age, congestive heart failure, hypertension, low hematocrit, and ventricular ejection fraction less than 40%. The patients at highest risk for developing CIN are those with both diabetes and pre-existing renal insufficiency. Other risk factors are concomitant exposure to chemotherapy, aminoglycoside or nonsteroidal anti-inflammatory agents, hyperuricemia, and diseases that affect renal hemodynamics, such as end-stage liver disease and nephrotic syndrome. Patients with a diagnosis of a paraproteinemia syndrome/disease (e.g., multiple myeloma), history of a kidney transplant, renal tumor, renal surgery, or single kidney may also be at higher risk of CIN.

The most common nonpatient-related causes are high osmolar contrast agents, ionic contrast, increased contrast viscosity, multiple contrast-enhanced studies performed within a short period, and large contrast volume infused (Pannu et al, 2006).

Despite significant discussion among radiologists and urologists, the literature does not support an absolute serum creatinine level that prohibits the use of contrast media. Prevention of CIN has been the subject of many research studies, and the results have been summarized by several different meta-analyses. In these meta-analyses the baseline serum creatinine of study participants ranged from 0.9 to 2.5 mg/dL. In one survey the policies regarding the cutoff value for serum creatinine varied widely among radiology practices. Thirty-five percent of respondents used 1.5 mg/dL, 27% used 1.7 mg/dL, and 31% used 2.0 mg/dL (mean, 1.78 mg/dL) as a cutoff value in patients with no risk factors other than elevated creatinine; threshold values were slightly lower in diabetic patients (mean, 1.68 mg/dL). Patients in end-stage renal disease who have no remaining natural renal function are no longer at risk for CIN and may receive LOCM or iso-osmolar contrast media (Elicker et al, 2006).

Prevention of CIN is of great concern and has been a subject of many different studies. Hydration is the major preventative action against CIN. Periprocedural IV hydration with 0.9% saline at 100 mL/hr 12 hours before to 12 hours after has been shown to decrease the incidence of CIN after IV contrast use (Solomon et al, 2007). The use of sodium bicarbonate has not been definitively shown to prevent CIN in patients receiving IV iodinated contrast material. (The use of N-acetylcysteine for the prevention of CIN is controversial) (Safirstein et al, 2000). Currently there is insufficient evidence to make a definitive recommendation for its use, and therefore it should not be considered a substitute for appropriate screening and hydration (Zoungas et al, 2009; Newhouse and RoyChoudhury, 2013). Furosemide was found to increase the risk of developing CIN (Pannu et al, 2006; Kelly et al, 2008).

Magnetic Resonance Imaging Contrast Agents

Because MRI offers previously unseen detailed soft tissue imaging compared with CT, it was initially believed that MRI would not require contrast enhancement. However, by 2005, almost 50% of MRI studies were being performed with contrast media. Extracellular MRI contrast agents contain paramagnetic metal ions. Copper, manganese, and gadolinium (Gd) were the potential paramagnetic ions for use with MRI. Gadolinium, however, is the most powerful with 7 unpaired electrons, but its toxicity required encapsulation by a chelate. Paramagnetic agents such as Gd are positive enhancers reducing the T1 and T2 relaxation times and increasing tissue signal intensity (SI) on T1-weighted images, while having little effect on T2-weighted images.

Gadolinium

Acute adverse reactions are encountered less frequently with Gd-based contrast media (GBCM) than after administration of iodinated contrast media. The frequency, of all acute adverse events after an injection of 0.1 or 0.2 mmol/kg of gadolinium chelate, ranges from 0.07% to 2.4%. The vast majority of these reactions are mild, including coldness at the injection site, nausea, emesis, headache, warmth or pain at the injection site, paresthesias, dizziness, and itching. Reactions resembling an “allergic” response occur with a frequency of 0.004% to 0.7%. Reactions consisting of rash, hives, or urticaria are most frequent; the patient rarely develops bronchospasm. Severe, life-threatening anaphylactoid or nonallergic anaphylactic reactions are exceedingly rare (0.0001% to 0.001%). In a meta-analysis of 687,000 Gd doses for MRI, only five reactions were severe. In another survey based on 20 million administered doses, 55 patients (0.0003%) had severe reactions. Fatal reactions to gadolinium chelate agents have been reported, but they are extremely rare (Murphy et al, 1999). There have been no documented vaso-occlusive or hemolytic complications when administering GBCM to patients with sickle cell disease (Elicker et al, 2006; Dillman et al, 2011). Gd agents are considered to have no nephrotoxicity at approved doses for MRI. However, because of the risk of nephrogenic systemic fibrosis (NSF) in patients with severe renal dysfunction, the use of Gd agents in this patient population requires some precaution and a review of the current recommendations.

Extracellular MRI agents are known to interfere with some serum chemistry assays. For example, serum calcium tests will often be measured as a false reading of hypocalcemia for 24 hours after MRI with Gd enhancement, even though serum calcium is actually in the normal range. Other tests including iron, magnesium, iron-binding capacity, and zinc may also have spurious results. Biochemical assessment is more reliable when performed 24 hours after exposure to Gd contrast media.

Nephrogenic Systemic Fibrosis

NSF is a fibrosing disease of the skin, subcutaneous tissues, lungs, esophagus, heart, and skeletal muscles. Initial symptoms typically include skin thickening and/or pruritus. Symptoms and signs may develop and progress rapidly, with some affected patients developing contractures and joint immobility within days of exposure. Death may result in some patients, presumably as a result of visceral organ involvement.

In 1997 NSF was described in dialysis patients who had not been exposed to GBCM. The condition was previously known as *nephrogenic fibrosing dermatopathy*. In 2006 independent reports surfaced defining a strong association with GBCM in patients with advanced renal disease (Cowper et al, 2000; Grobner, 2006; Marckmann et al, 2006). It is now currently accepted that GBCM exposure is a necessary factor in the development of NSF. Onset of NSF varies between 2 days and 3 months, with rare cases appearing years after exposure (Shabana et al, 2008). Early manifestations include subacute swelling of distal extremities, followed by severe skin induration and later even organ involvement. In a 2007 survey performed by the ACR, 156 cases of NSF were reported by 27 responding institutions; 140 of these 156 patients were known to have received GBCM. In 78 patients, the specific GBCM was known. Forty-five of them received gadodiamide, 17 gadopentetate dimeglumine, 13 gadoversetamide, and three gadobenate dimeglumine. NSF following gadoteridol administration has also been reported. Many of the cases in which agents other than gadodiamide and gadopentetate dimeglumine were used are confounded by the fact that affected patients were injected with other agents as well (American College of Radiology, 2013). Between 12% and 20% of confirmed cases of NSF occurred in patients with acute kidney injury. Patients with chronic kidney disease have a 1% to 7% chance of developing NSF after MRI with Gd agents (Todd et al, 2007).

Patients with a glomerular filtration rate (GFR) less than 30 mL/min/1.73 m² not on chronic dialysis are the most difficult patient population in terms of choosing imaging modality. They are at risk for CIN if exposed to iodinated contrast media for CT imaging and are also at significant risk of developing NSF if exposed to GBCM during MRI. Recent data suggest that the risk of NSF may be greatest in patients with a GFR of less than 15 mL/min/1.73 m². These patients have a 1% to 7% chance of developing NSF after exposure to GBCM during MRI, with the incidence being much less in patients with GFRs that are higher (Kanal et al, 2008). In patients with chronic kidney disease, it is recommended that contrast media be avoided if possible. If MRI contrast media is absolutely essential, use of the lowest possible doses (needed to obtain a diagnostic study) of selected GBCM is recommended. In this setting, patients should be informed of the risks of GBCM administration and must give their consent to proceed. There is no proof that any GBCM is completely safe in this patient group; however, some have suggested avoiding gadodiamide and considering use of macrocyclic agents (Kanal et al, 2008). Patients with chronic kidney disease but GFR more than 30 mL/min/1.73 m² are considered to be at extremely low or no risk for developing NSF if a dose of GBCM of 0.1 mmol/kg or less is used. Patients with GFR more than 60 mL/min/1.73 m² do not appear to be at increased risk of developing NSF, and the current consensus is that all GBCM can be administered safely to these patients. In their publications, the ACR stresses that the current information on NSF and its relationship to GBCM administration is very preliminary and further research is needed to better understand this potentially devastating complication.

KEY POINTS: CONTRAST MEDIA

- Type 2 diabetic patients with renal insufficiency who are receiving oral metformin biguanide hyperglycemic therapy are at risk for developing biguanide lactic acidosis after exposure to intravascular radiologic contrast media; they should stop metformin the day before the procedure and restart 48 hours after if they have a normal or baseline serum creatinine.
- Patients at risk for adverse reaction to contrast include those with previous adverse reactions, history of asthma, severe cardiac disease, renal insufficiency, dehydration, sickle cell anemia, anxiety, apprehension, hyperthyroidism, and presence of adrenal pheochromocytoma.
- Epinephrine can be administered IV in the dose of 0.01 mg/kg of 1:10,000 dilution or 0.1 mL/kg slowly into a running infusion of saline and can be repeated every 5 to 15 minutes as needed. If no IV access is available, the recommended IM dose of epinephrine is 0.01 mg/kg of 1:1000 dilution (or 0.01 mL/kg to a maximum of 0.15 mg of 1:1000 if less than 30 kg; 0.3 mg if weight is greater than 30 kg) injected in the lateral thigh.
- Patients at greatest risk for contrast-induced nephropathy are those with diabetes mellitus and dehydration.
- Steroids given to prevent adverse contrast agents should be given at least 6 hours before injection.

INTRAVENOUS UROGRAPHY

Once the mainstay of urologic imaging, the intravenous excretory urographic (IVU) study has essentially been replaced by CT and MRI. With the ability of new scanners to perform axial, sagittal, and coronal reconstruction of the upper tract urinary system, essentially all of the data and information obtained by traditional IVU can be realized with CT imaging. In addition, some parenchymal defects, cysts, and tumors can be better delineated with CT than with IVU.

Figure 2-2. Intravenous excretory urogram (IVU) in a 40-year-old woman with the complaint of a mobile mass in the right lower quadrant with standing associated with bilateral flank and back pain that resolved in the supine position. A, Supine IVU shows kidneys in the normal position with normal ureters and proximal collecting systems. B, Standing film shows significant displacement of both kidneys, with the right kidney moving onto the pelvis as described by the patient.

Technique

Bowel prep may help to visualize the entire ureters and upper collecting systems. Patients with chronic constipation may benefit most from complete bowel prep with clear liquids for 12 to 24 hours and an enema 2 hours before the procedure.

Before injection of contrast, a scout radiograph or KUB (kidney-ureter-bladder) film is taken demonstrating the top of the kidneys and the entire pelvis to the pubic symphysis. This allows determination of adequate bowel prep, confirms correct positioning, and exposes kidney stones or bladder stones.

Contrast is injected as a bolus of 50 to 100 mL of contrast. The nephrogenic phase is captured with a radiograph immediately after injection. In the past, tomograms were used to look for parenchymal defects, but now CT or MRI is preferred. A film is taken at 5 minutes and then additional films at 5-minute intervals until the question that prompted the IVU is answered. Abdominal compression may be used to better visualize the ureters. Occasionally, oblique films will be used to better define the course of the ureter in the bony pelvis and to precisely differentiate ureteral stones from pelvic calcifications.

Upright films may be helpful in certain situations. In the rare case of suspected symptomatic renal ptosis, IVU can be particularly helpful (Fig. 2-2). Supine films are compared with upright films to measure the degree of ptosis. Such a comparison cannot be made with MRI or CT imaging. In the case of calyceal stones or milk of calcium stones, layering of the contrast can be helpful to evaluate the anatomy of the calyx harboring the stones.

Postvoid films are obtained to evaluate the presence of outlet obstruction, prostate enlargement, and bladder filling defects, including stones and urothelial cancers.

Indications

1. Demonstration of renal collecting systems and ureters
2. Investigation of level of ureteral obstruction
3. Demonstration of intraoperative opacification of collecting system during extracorporeal shock wave lithotripsy or percutaneous access to the collecting system
4. Demonstration of renal function during emergent evaluation of unstable patients

5. Demonstrate renal and ureteral anatomy in special circumstances (e.g., ptosis, after transureteroureterostomy, and after urinary diversion)

PLAIN ABDOMINAL RADIOGRAPHY

The plain abdominal radiograph is a conventional radiography study, which is intended to display the kidneys, ureters, and bladder. The plain abdominal radiograph may be employed as a primary study or a scout film in anticipation of contrast media. Plain films are widely used in the management of renal calculus disease. Plain radiography is also useful in evaluation of the trauma patient because it can be performed as a portable study in the trauma unit. Secondary findings on plain radiography, such as rib fractures, fractures of the transverse processes of the vertebral bodies, and pelvic fractures, may indicate serious associated urologic injuries.

Technique

An abdominal plain radiograph is obtained with the patient in the supine position, using an anterior to posterior exposure. The study typically includes that portion of the anatomy from the level of the diaphragm to the inferior pubic symphysis. It may occasionally be necessary to make two exposures to cover the desired anatomic field. Depending on the indication for the study, oblique films are obtained to clarify the position of structures in relation to the urinary tract. If small bowel obstruction or free peritoneal air is suspected, upright films will be obtained.

Indications

1. Used as a preliminary film in anticipation of contrast administration
2. Assessment of presence of residual contrast from a previous imaging procedure
3. Assessment of renal calculus disease before and after treatment
4. Assessment of the position of drains and stents
5. Used as an adjunct to the investigation of blunt or penetrating trauma to the urinary tract

Figure 2-3. A, Right ureteral calculus (arrow) overlying the sacrum is difficult to visualize on the plain film. B, The right posterior oblique study fails to confirm the location of the ureteral calculus. C, Computed tomography confirms this 6-mm calculus in the right ureter at the level of the third sacral segment (arrow).

Limitations

Although plain film radiography is often used in the evaluation of renal colic, it is unreliable in the demonstration of calculus disease for a variety of reasons: (1) overlying stool and bowel gas may obscure small calculi; (2) stones may be obscured by other structures such as bones or ribs (Fig. 2-3); (3) calcifications in pelvic veins or vascular structures may be confused with ureteral calculi; and (4) stones that are poorly calcified or composed of uric acid may be radiolucent. Nevertheless, plain film radiography is very valuable in assessing the suitability of a patient for extracorporeal shock wave lithotripsy because the ability to identify the stone on fluoroscopy is critical to targeting. Furthermore, a KUB is very cost-effective for monitoring residual stone burden after treatment (Fig. 2-4). For complex pathology of the urinary tract, plain abdominal radiography has been supplanted by axial imaging. Plain radiography has a very limited role in evaluating soft tissue abnormalities of the urinary tract.

RETROGRADE PYELOGRAPHY

Retrograde pyelograms are performed to opacify the ureters and intrarenal collecting system by the retrograde injection of contrast media. Any contrast media that can be used for excretory urography is also acceptable for retrograde pyelography. Attempts should be made to sterilize the urine before retrograde pyelography because there is a risk of introducing bacteria into the upper urinary tracts or into the bloodstream. Although many studies are able to document the presence or absence of dilation of the ureter, retrograde pyelography has the unique ability to document the normalcy of the ureter distal to the level of obstruction and to better define the extent of the ureteral abnormality.

Technique

Retrograde pyelography is usually performed with the patient in the dorsal lithotomy position. An abdominal plain radiograph (scout film) is obtained to ensure that the patient is in the appropriate position to evaluate the entire ureter and intrarenal collecting system. Cystoscopy is performed and the ureteral orifice is identified.

Contrast may be injected through either a nonobstructing catheter or an obstructing catheter. Nonobstructing catheters include whistle tip, spiral tip, or open-ended catheters. Use of nonobstructing catheters allows passage of the catheter into the ureter and up to the collecting system, over a guidewire if necessary. Contrast can then be introduced directly into the upper collecting system and the

Figure 2-4. KUB (kidney-ureter-bladder) film demonstrating residual stone fragments (arrows) adjacent to a right ureteral stent 1 week following right extracorporeal shock wave lithotripsy.

ureters visualized by injection of contrast as the catheter is withdrawn.

The other commonly employed method is the use of an obstructing ureteral catheter such as a bulb-tip, cone-tip, or wedge-tip catheter. These catheters are inserted into the ureteral orifice and then pulled back against the orifice to effectively obstruct the ureter. Contrast is then injected to opacify the ureter and intrarenal collecting system. Depending on the indication for the study, it is useful to dilute the contrast material (to 50% or less) with sterile fluid. This prevents subtle filling defects in the collecting system or ureter from being obscured. Care should be taken to evacuate air bubbles from the syringe and catheter before injection. Such air bubble artifacts could be mistaken for stones or tumors.

Figure 2-5. A, Right retrograde pyelogram performed using an 8-Fr cone-tipped ureteral catheter and dilute contrast material. The ureter and intrarenal collecting system are normal. B, Left retrograde pyelogram using an 8-Fr cone-tipped ureteral catheter. A filling defect in the left distal ureter (arrow) is a low-grade transitional cell carcinoma. The ureter demonstrates dilation, elongation, and tortuosity, the hallmarks of chronic obstruction.

After air is expelled from the catheter into the bladder, the ureteral orifice is intubated. Contrast is injected slowly, usually requiring 5 to 8 mL to completely opacify the ureter and intrarenal collecting system in adults (Fig. 2-5). More or less contrast may be required, depending on the size of the patient and the capaciousness of the collecting system. Limited use of fluoroscopy while injecting will help prevent overdistention of the collecting system and reduce the risk of extravasation of contrast.

Historically, when a retrograde pyelogram consisted of a series of radiographs taken at intervals, it was important to document various stages of filling and emptying of the ureter and collecting systems. Because of peristalsis the entire ureter will often not be seen on any given static exposure or view. With current equipment, including tables which incorporate fluoroscopy, it is possible to evaluate the ureter during peristalsis in real time, thus reducing the need for static image documentation. Documentary still images or “spot films” may be saved for future comparison. Urologists interpret retrograde pyelograms in real time as they are performed.

Indications

1. Evaluation of congenital ureteral obstruction
2. Evaluation of acquired ureteral obstruction
3. Elucidation of filling defects and deformities of the ureters or intrarenal collecting systems
4. Opacification or distention of collecting system to facilitate percutaneous access
5. In conjunction with ureteroscopy or stent placement
6. Evaluation of hematuria
7. Surveillance of transitional cell carcinoma
8. Evaluation of traumatic or iatrogenic injury to the ureter or collecting system

Limitations

Retrograde pyelography may be difficult in cases where the bladder is involved with diffuse inflammation or neoplastic changes, especially when bleeding is present. Identification of the ureteral orifices may be facilitated in such cases by the IV injection of indigotindisulfonate sodium or methylene blue. Changes associated with bladder outlet obstruction may result in angulation of the

intramural ureters. This may make cannulation with an obstructing catheter quite difficult. Attempts to cannulate the ureteral orifice may result in trauma to the ureteral orifice and extravasation of contrast material into the bladder wall. The potential for damage to the intramural ureter must be weighed against the potential information to be obtained by the retrograde pyelogram.

Complications

Backflow occurs during retrograde pyelography when contrast is injected under pressure and escapes the collecting system. Contrast may escape the collecting system by one of four routes: **Pyelotubular** backflow occurs when contrast fills the distal collecting ducts producing opacification of the medullary pyramids (Fig. 2-6A). **Pyelosinus** backflow occurs when a tear in the calyces at the fornix allows contrast to leak into the renal sinus (Fig. 2-6B). **Pyelolymphatic** backflow is characterized by opacification of the renal lymphatic channels (Fig. 2-6C). **Pyelovenous** backflow is seen when contrast enters the venous system, resulting in visualization of the renal vein.

Although backflow does not usually cause measurable clinical harm, the potential implications of backflow include (1) introduction of bacteria from infected urine into the vascular system and (2) the absorption of contrast media, which could result in adverse reactions in susceptible patients. It has been demonstrated that the risk of significant urinary tract infection is only about 10% and the risk of sepsis is low when antibiotic prophylaxis therapy is administered before endoscopic procedures (including retrograde pyelography) (Christiano et al, 2000). Although contrast reactions are rare with retrograde pyelography, they have been reported (Johanning, 1980; Weese et al, 1993). In patients with documented severe contrast allergy, prophylactic pretreatment may be appropriate. In those patients considered at risk, care should be taken to inject under low pressures to minimize the probability of backflow and absorption of the contrast into the vasculature system.

LOOPOGRAPHY

Loopography is a diagnostic procedure performed in patients who have undergone urinary diversion. Historically the term

Figure 2-6. Patterns of backflow during retrograde pyelography. A, Pyelotubular backflow. B, Pyelosinus backflow. C, Pyelolymphatic backflow.

Figure 2-7. Loopogram in a patient with epispadias/exstrophy and ileal conduit urinary diversion. The plain film (A) shows wide diastasis of the pubic symphysis. After contrast administration via a catheter placed in the ileal conduit, free reflux of both ureterointestinal anastomoses is demonstrated (B). A postdrain radiograph (C) demonstrates persistent dilation of the proximal loop, indicating mechanical obstruction of the conduit (arrows).

“loopogram” has been associated with ileal conduit diversion but may be used in reference to any bowel segment serving as a urinary conduit. When imaging patients with a continent diversion involving a reservoir or neobladder, “pouch-o-gram” would be more accurately descriptive. Because an ileal conduit urinary diversion usually has freely refluxing ureterointestinal anastomoses, the ureters and upper collecting systems may be visualized. In other forms of diversion, the ureterointestinal anastomoses may be purposely nonrefluxing. In such circumstances, when opacification of the upper urinary tract is desirable, antegrade ureteral imaging such as IVU, CT or MRI urography, or antegrade nephrostography may be required. When the patient has compromised renal function or is allergic to iodinated contrast material, loopogram can be performed with a low risk of systemic absorption (Hudson et al, 1981).

Technique

The patient is positioned supine. An abdominal plain radiograph is obtained before the introduction of contrast material (Fig. 2-7A). A commonly employed technique is to insert a small-gauge catheter

into the ostomy of the loop, advancing it just proximal to the abdominal wall fascia. The balloon on such a catheter can then be inflated to 5 to 10 mL with sterile water. By gently introducing contrast through the catheter, the loop can be distended, usually producing bilateral reflux into the upper tracts. Oblique films should be obtained in order to evaluate the entire length of the loop (Fig. 2-7B). Because of the angle at which many loops are constructed, a traditional anteroposterior (AP) view will often show a foreshortened loop and could miss a substantial pathology. A drain film should be obtained (Fig. 2-7C). This may demonstrate whether there is obstruction of the conduit.

Indications

1. Evaluation of infection, hematuria, renal insufficiency, or pain after urinary diversion
2. Surveillance of upper urinary tract for obstruction
3. Surveillance of upper urinary tract for urothelial neoplasia
4. Evaluation of the integrity of the intestinal segment or reservoir

RETROGRADE URETHROGRAPHY

A retrograde urethrogram is a study to evaluate the anterior and posterior urethra. Retrograde urethrography may be particularly beneficial in demonstrating the total length of a urethral stricture that cannot be negotiated by cystoscopy. Retrograde urethrography also demonstrates the anatomy of the urethra distal to a stricture that may not be assessable by voiding cystourethrography. Retrograde urethrography may be performed in the office or in the operating room before performing visual internal urethrotomy or formal urethroplasty.

Technique

A plain film radiograph is obtained before injection of contrast. The patient is usually positioned slightly obliquely to allow evaluation of the full length of urethra. The penis is placed on slight tension. A small catheter may be inserted into the fossa navicularis with the balloon inflated to 2 mL with sterile water. Contrast is then introduced via a catheter-tipped syringe. Alternatively, a penile clamp (e.g., Brodney clamp) may be used to occlude the urethra around the catheter (Fig. 2-8).

Indications

1. Evaluation of urethral stricture disease
 - a. Location of stricture
 - b. Length of stricture

2. Assessment for foreign bodies
3. Evaluation of penile or urethral penetrating trauma
4. Evaluation of traumatic gross hematuria

STATIC CYSTOGRAPHY

Static cystography is used primarily to evaluate the structural integrity of the bladder. The shape and contour of the bladder may give information about neurogenic dysfunction or bladder outlet obstruction. Filling defects such as tumors and stones may be appreciated.

Technique

The patient is positioned supine. A plain radiograph is performed to evaluate for stones and residual contrast and to confirm position and technique. The bladder is filled with 200 to 400 mL of contrast, depending on bladder size and patient comfort. Adequate filling is important to demonstrate intravesical pathology or bladder rupture. Oblique films should be obtained because posterior diverticula or fistulae may be obscured by the full bladder. A postdrainage film completes the study (Fig. 2-9).

Indications

1. Evaluation of intravesical pathology
2. Evaluation of bladder diverticula

Figure 2-8. Normal retrograde urethrogram demonstrating (A) the balloon technique for retrograde urethrography and (B) Brodney clamp (arrowhead) technique; note the bulbar urethral stricture (arrow). C, Normal structures of the male urethra as seen on retrograde urethrogram.

Figure 2-9. The patient has undergone radical retropubic prostatectomy. A, During bladder filling, contrast is seen adjacent to the vesicoureteral anastomoses (arrow). B, The postdrain film clearly demonstrates a collection of extravasated contrast (arrow).

3. Evaluation of inguinal hernia involving the bladder
4. Evaluation of colovesical or vesicovaginal fistulae
5. Evaluation of bladder or anastomotic integrity after surgical procedure
6. Evaluation of blunt or penetrating trauma to the bladder

Limitations

Abdominal and pelvic CT is so commonly used in the evaluation of blunt or penetrating trauma to the abdomen that CT cystography is often performed in conjunction with the trauma evaluation. However, studies have shown that conventional static cystography is as sensitive as CT cystography in detecting bladder rupture (Quagliano et al, 2006; Broghammer and Wesells, 2008).

VOIDING CYSTOURETHROGRAM

A voiding cystourethrogram (VCUG) is performed to evaluate the anatomy and physiology of the bladder and urethra. The study provides valuable information regarding the posterior urethra in pediatric patients. VCUG has long been used to demonstrate vesicoureteral reflux.

Technique

The study may be performed with the patient supine or in a semiupright position using a table capable of bringing the patient into the full upright position. A preliminary pelvic plain radiograph is obtained. In children, a 5- to 8-Fr feeding tube is used to fill the bladder to the appropriate volume. Patient comfort should be taken into account when determining the appropriate volume. In the adult population a standard catheter may be placed and the bladder filled to 200 to 400 mL. The catheter is removed and a film is obtained. During voiding, AP and oblique films are obtained. The bladder neck and urethra may be evaluated by fluoroscopy during voiding. Bilateral oblique views may demonstrate low-grade reflux, which is not able to be appreciated on the AP film. In addition, oblique films will demonstrate bladder or urethral diverticula, which are not always visible in the straight AP projection. Postvoiding films should be performed (Fig. 2-10).

Indications

1. Evaluation of structural and functional bladder outlet obstruction
2. Evaluation of reflux
3. Evaluation of the urethra in males and females

Limitations

This study requires bladder filling using a catheter. This may be traumatic in children and difficult in some patients with anatomic abnormalities of the urethra or bladder neck. Filling of the bladder may stimulate bladder spasms at low volumes and some patients are unable to hold adequate volumes for investigation. **Bladder filling in patients with spinal cord injuries higher than T6 may precipitate autonomic dysreflexia (Barbaric, 1976; Fleischman and Shah, 1977; Linsenmeyer et al, 1996).**

NUCLEAR SCINTIGRAPHY

Radionuclide imaging is the procedure of choice to evaluate renal obstruction and function. It is very sensitive to changes that induce focal or global changes in kidney function. Because neither Gd nor iodinated IV contrast agents are used, scintigraphy does not damage the kidney, has no lingering toxicity, results in minimal absorbed radiation, and is free from allergic reactions. Compared to other diagnostic imaging studies such as retrograde pyelogram, renal scintigraphy is noninvasive, has minimal risk and minimal discomfort, and allows determination of the function of the kidney.

Once the agent is injected IV, gamma scintillation cameras measure radiation emitted from the radioisotope, and digital work stations gather, process, and display the information. There is an extensive list of radiopharmaceuticals used for renal scintigraphy. This section will be limited to those agents most commonly used in urologic practice.

Technetium 99m-diethylenetriamine pentaacetic acid (^{99m}Tc -DTPA) is primarily a glomerular filtration agent (Peters, 1998; Gates, 2004). It is most useful for evaluation of obstruction and renal function. Because it is excreted through the kidney and dependent on GFR, it is less useful in patients with renal failure because impaired GFR may limit adequate evaluation of the collecting

Figure 2-10. A voiding cystourethrogram performed for the evaluation of recurrent urinary tract infection in this female patient. A, An oblique film during voiding demonstrates thickening of the midureteral profile (arrows). B, After interruption of voiding, a ureteral diverticulum is clearly visible extending posteriorly and to the left of the midline (arrows).

system and ureters. It is readily available and relatively inexpensive (Klopper et al, 1972).

Technetium 99m-dimercaptosuccinic acid (^{99m}Tc -DMSA) is cleared by both filtration and secretion. It localizes to the renal cortex with very little accumulation in the renal papilla and medulla (Lin et al, 1974). Therefore it is most useful for identifying cortical defects and ectopic or aberrant kidneys. With these properties, ^{99m}Tc -DMSA can distinguish a benign functioning abnormality in the kidney from a space-occupying malignant lesion, which would not have normal renal function. No valuable information on the ureter or collecting system can be obtained with ^{99m}Tc -DMSA, but it remains a standard for renal cortical imaging.

Technetium 99m-mercaptoacetyl triglycine (^{99m}Tc -MAG3) is an excellent agent for imaging because of its photon emission, 6-hour half-life, and ease of preparation. It is cleared mainly by tubular secretion (Fritzberg et al, 1986). A small amount, approximately 10%, of ^{99m}Tc -MAG3, is excreted by extrarenal means, and most of this is hepatobiliary excretion (Eshima et al, 1990; Itoh, 2001). Because it is extensively bound to protein in plasma, it is limited in its ability to measure GFR, but it is an excellent choice for patients with renal insufficiency and urinary obstruction. The tracer is well suited for evaluation of renal function and diuretic scintigraphy. Also, it is an excellent tracer to evaluate renal plasma flow.

Diuretic Scintigraphy

Nuclear medicine imaging plays a crucial role unmet by CT, MRI, or ultrasonography in the diagnosis of upper tract obstruction, and its unique characteristics provide noninvasive information regarding dynamic renal function. The diuretic renal scan using ^{99m}Tc -MAG3 is able to provide differential renal function and clearance time comparing right and left kidneys, which is pivotal in patient management. The initial phase is the flow phase where 2-second images are gathered for 2 minutes and then 1-second images for 60 seconds. The flow phase shows renal uptake, background clearance, and abnormal vascular lesions, which may indicate arteriovenous

malformations, tumors, or active bleeding. In the second phase, the renal phase, time-to-peak uptake is typically between 2 and 4 minutes. The renal phase is the most sensitive indicator of renal dysfunction. One-minute images are taken for 30 minutes. In the final phase, the excretory phase, 1-minute images are taken for 30 minutes. A diuretic (usually furosemide 0.5 mg/kg) is administered when maximum collecting system activity is visualized. The $T_{1/2}$ is the time it takes for collecting system activity to decrease by 50% from that at the time of diuretic administration. This is highly technician dependent because the diuretic must be given when the collecting system is displaying maximum activity. Transit time through the collecting system in less than 10 minutes is consistent with a normal, nonobstructed collecting system. $T_{1/2}$ of 10 to 20 minutes shows mild to moderate delay and may be a mechanical obstruction. The patient's perception of pain after diuretic administration can be helpful for the treating urologist to consider when planning surgery in the patient with mild to moderate obstruction. A $T_{1/2}$ of greater than 20 minutes is consistent with a high-grade obstruction. The level of obstruction can usually be determined, as can abnormalities such as ureteral duplication (Ell and Gambhir, 2004). A normal renal scan is shown in Figure 2-11.

Hepatobiliary excretion can cause false-positive readings if the area of intestinal activity or gallbladder activity is included in the area of interrogations during the study (Fig. 2-12).

The diuretic renal scan is another imaging study where communication with the interpreting physician is vital for correct performance of the test, as well as appropriate interpretation. For example, there are times when patients with unilateral or bilateral ureteral stents are sent for diuretic scintigraphy to determine differential renal function. If a bladder catheter is not placed and open to drainage during the diuretic renal scan, the radiopharmaceutical excreted from the healthy kidney may wash up into or back flow via the ureteral stent into the stented kidney, giving the false-positive appearance to have more function than is physiologically present. This false-positive test may lead to inappropriately reconstructing a kidney that in reality has little or insufficient function.

Figure 2-11. A, Technetium 99m-mercaptoacetyl triglycine (^{99m}Tc -MAG3) perfusion images demonstrate normal, prompt, symmetrical blood flow to both kidneys. B, Perfusion time-activity curves demonstrate essentially symmetrical flow to both kidneys. Note the rising curve typical of ^{99m}Tc -MAG3 flow studies. Dynamic function images demonstrate good uptake of tracer by both kidneys and prompt visualization of the collecting systems. This renogram demonstrates prompt peaking of activity in both kidneys. The downslope represents prompt drainage of activity from the kidneys. The printout of quantitative data shows the differential renal function to be 47% on the left, 53% on the right. The normal half-life for drainage is less than 20 minutes when ^{99m}Tc -MAG3 is used. The $T_{1/2}$ is 5 minutes on the left and 7 minutes on the right consistent with both kidneys being unobstructed.

Figure 2-12. Delayed static images in the posterior and anterior projections demonstrate intestinal activity (arrow in A) and gallbladder activity (arrow in B), reflecting a normal mode of excretion of technetium 99m-mercaptoacetyl triglycine (^{99m}Tc -MAG3). Gallbladder activity, in particular, can cause false-positive interpretation when it overlies activity in the renal collecting system or is inappropriately included in the area of interrogation. Liver activity is variable and tends to be more pronounced in children and patients with renal insufficiency.

Nuclear Medicine in Urologic Oncology

Whole-Body Bone Scan

Conventional radionuclide imaging in urologic malignancy has long been the standard for detecting bone metastasis. The whole-body bone scan or skeletal scintigraphy is the most sensitive method for detecting bone metastasis (Narayan et al, 1988). A “positive” bone scan is not specific for cancer and may require plain film radiography, CT, or MRI to confirm, as well as correlation with prior history of bone fractures, trauma, surgery, or arthritis. In patients with diffuse metastatic bone involvement, the bone scan can be mistaken for normal because there is uniformly increased uptake in the bony structures (Kim et al, 1991).

Positron Emission Tomography

The most recent advance in nuclear scintigraphy is in the detection of primary and metastatic cancer using positron emission tomography (PET). Depending on the radiotracer used, PET offers diagnostic information based on glucose, choline, or amino acid metabolism and has also been applied to imaging tumor cell proliferation and tissue hypoxia in urologic malignancies. The diagnostic performance of fluorodeoxyglucose (FDG)-PET is hampered by the renal excretion of FDG and by the low metabolic activity often seen in tumors such as prostate cancer. However, new PET tracers including radiolabeled choline and acetate may offer an alternative approach. There is consistent evidence that FDG-PET provides important diagnostic information in detecting metastatic and recurrent germ cell tumors, and it might offer additional information in the staging and restaging of bladder and renal cancer (Powles et al, 2007; Rioja et al, 2010).

Molecular imaging with PET may help individualize the surgical and medical care of urologic oncology patients. PET is certainly having an impact in general oncology and is being actively investigated for use in urologic malignancies. PET provides unique insights into molecular pathways of diseases. PET using ^{18}F -FDG has gained increasing acceptance for the diagnosis, staging, and treatment monitoring of various tumor types.

There are data on the use of PET/CT in testis cancer, where PET/CT was found to have a higher diagnostic accuracy than CT for staging and restaging in the assessment of a CT-visualized residual mass following chemotherapy for seminoma and non-seminomatous germ cell tumors (Albers et al, 1999; Hain et al, 2000). There may be a role for detection of recurrent nonteratoma disease and the assessment of residual masses after chemotherapy. In a series of seminoma patients who were evaluated after chemotherapy for residual retroperitoneal masses, PET was accurate in 14 of 14 patients with tumors greater than 3 cm and in 22 of 23 patients with lesions less than 3 cm. Overall the sensitivity and specificity was 89% and 100%, respectively (De Santis et al, 2004). The accuracy of PET seems to be compromised if performed within 2 weeks of completion of chemotherapy, likely because of decreased metabolism and increased macrophage activity (Eary, 1999). It is recommended that PET/CT be delayed for 4 to 12 weeks following completion of chemotherapy (Shvarts et al, 2002).

PET/CT may have a promising role in clear cell renal cell carcinoma. An antibody (cG250) recognizing carbonic anhydrase IX has been developed. Carbonic anhydrase IX is a protein related to the unrestrained growth of clear cell renal cancers. A positron-emitting radionuclide (iodine 124) has been attached to the cG250 antibody and injected into renal cell cancer patients. The radionuclide antibody complex attaches to the carbonic anhydrase IX protein from

clear cell renal cancer cells and can be detected on PET/CT imaging. Using this scheme in 26 patients with renal tumors, there was 94% sensitivity and 100% specificity in renal cell carcinoma before surgery (Larson and Schöder, 2008).

There are at least seven tracers being investigated for detection of metastatic prostate cancer. Each tracer is directed at a different part of cell function such as glycolysis, amino acid transport, choline kinase activity, fatty acid synthesis, androgen receptor, and bone mineralization. FDG as a PET tracer was investigated in 91 patients with prostate-specific antigen (PSA) recurrence after radical prostatectomy. FDG-PET was able to detect local or systemic recurrence in only 34% of patients (Schöder et al, 2005).

Very few studies have addressed the use of PET in bladder cancer. FDG is renal excreted and not useful in bladder cancer. Only 78% of bladder cancer could be visualized using ^{11}C -methionine tracer and PET did not improve local staging of the disease. ^{11}C -choline was also found to be a poor predictor of primary or metastatic urothelial carcinoma (Ahlstrom et al, 1996; de Jong et al, 2002).

PET is still in the early stages of investigation for urologic tumors. The exact role in the practice of urology has yet to be determined but will certainly have a great role in the future as more tracers specific to urologic cancers are discovered. Using the combination of nuclear imaging and ever-increasing knowledge about cancer cell biology, radiotracers have been developed to be incorporated into dividing cells or cellular mechanisms involved in the increased metabolic activity of malignancies, which can then be detected using PET imaging. Combining PET with high-resolution CT has the ability to increase our detection of recurrent or metastatic urologic cancers. Many different isotopes are being investigated for the detection of metastatic disease.

KEY POINTS: NUCLEAR SCINTIGRAPHY

- During diuretic renal scan, the diuretic must be given when maximum activity is seen in the kidney.
- An elimination $T_{1/2}$ less than 10 minutes is an unobstructed system, and a $T_{1/2}$ greater than 20 minutes is consistent with high-grade obstruction.
- If ureteral stents are in place, patients undergoing diuretic renal scan should have an unclamped bladder catheter in place during the study.
- ^{99m}Tc -MAG3 is the agent of choice for diuretic renal scan to determine differential renal function and obstruction.

COMPUTED TOMOGRAPHY

The 1979 Nobel Prize in Medicine and Physiology was awarded to Allan M. Cormack and Sir Godfrey N. Hounsfield for the development of computer-assisted tomography. While basic principles remain the same, significant advances over the past 35 years have resulted in the development of multidetector CT devices, improving soft tissue detail and allow the possibility of rapid three-dimensional (3D) reconstruction of the entire genitourinary system.

CT has become one of the most integral parts of urologic practice, and the CT urogram (CTU) has replaced IVU as the imaging modality of choice in modern urology for the workup of hematuria, urologic malignancies, detection of kidney stones, and preoperative planning. As in the case of conventional radiographic imaging, the basis for CT imaging is the attenuation of x-ray photons as they pass through the patient. Tomography is an imaging method that produces 3D images of internal structures by recording the passage of x-rays as they pass through different body tissues. In the case of CT, a computer reconstructs cross-sectional images of the body based on measurements of x-ray transmission through thin slices of the body tissue (Brant, 1999). A collimated x-ray beam is generated on one side of the patient, and the amount of transmitted radiation is measured by a detector placed on the opposite side of the x-ray

beam. These measurements are then repeated systematically, while a series of exposures from different projections is made as the x-ray beam rotates around the patient. The result is production of a 3D image of internal structures in the human body by recording the passage of different energy waves through various internal structures. Data collected by the detectors are reconstructed by computerized algorithms to result in a viewable tomographic display.

There are several different imaging variables that are adjusted to allow adequate, detailed image resolution while minimizing the time on the scanner and limiting exposure to radiation. The variable application of pitch, beam collimation, detector size, and tube voltage are used by the radiologist and imaging technologist for ideal image requisition. A detailed description of each of these variables is beyond the scope of this chapter (see [Suggested Readings](#)).

Perhaps the greatest recent advancement in CT is the use of helical image acquisition techniques with multichannel or multidetectors (MDCT). In a helical CT the patient moves through a continuously rotating gantry. The helical raw images are processed using interpolation algorithms in order to visualize the internal structures as sagittal, coronal, or axial reconstructed images. The "single slice spiral CT," introduced in 1988, had a single row of detectors and required multiple passes to visualize a small area of interrogation. The standard scanners in use today have between 64 and 320 rows of detectors, which allow the patient's entire body to be imaged during a single breath hold, with few or no motion artifacts, more precise diagnostic accuracy, increased concentration of contrast material, shorter scanning time, less radiation exposure, and significant increase in anatomic coverage with a single scan. CT scanners with 750 rows of detectors are currently being developed. For example, in one second, a 320-slice CT scanner can image slices as large as 16 cm (6.3 inches), capturing all of the body's organs in a single rotation of the central x-ray-emitting gantry (Wang et al, 1994; Mahesh, 2002) (Fig. 2-13).

Readily available software is capable of 3D processing of CT images to recreate the urinary system. These 3D images offer improved preoperative planning, appreciation of proximity to adjacent organs, the ability to define vasculature, and improved communication with patients, who can now easily see their particular pathology and better appreciate the challenges faced by their surgeon (Fig. 2-14).

Dual-source CT (DSCT) is a relatively new technique used for diagnostic imaging, using two rotating tubes to acquire both high- and low-voltage images allowing tissue differentiation, visualization of tendons and ligaments, improved CT angiography, and differentiation of kidney stones based on stone composition (Coursey et al, 2010). Using DSCT, a reliable distinction can be made between uric acid and calcium oxalate and between brushite and uric acid stones (Ferrandino et al, 2010; Botsikas et al, 2013).

Real-time CT fluoroscopy is now available as an option on new CT imaging equipment. CT fluoroscopy gives a 3D CT image that is much more detailed and offers greater soft tissue contrast and resolution than conventional CT. The most common use in urology is for biopsy of the kidney. CT fluoroscopy helps to overcome movement of the kidney during respiratory variation. It also has been used for fluid aspiration, drain placement, catheter placement, percutaneous cryoablation, and radiofrequency (RF) ablation of renal tumors. **One significant disadvantage of CT fluoroscopy is the increased radiation exposure to the patient and radiologist or surgeon performing the procedure** (Daly et al, 1999; Keat, 2001; Gupta et al, 2006).

The CTU is an excretory urography in which the MDCT is used for imaging of the urinary tract. It is indicated in the workup of hematuria, kidney stones, renal masses, renal colic, and urothelial tumors. The CT scan examination starts with the physician's request for imaging. Radiologists around the world appreciate a brief description from the urologist of the question to be answered by the CT scan. Equipped with a better understanding of why the CT was ordered, the radiologist and the CT technician can adjust different CT variables and choose the appropriate contrast media needed to deliver a valuable report back to the ordering urologist.

Figure 2-13. A, A computed tomography scanner with a single-row detector requires five circular passes around the patient to image a small area of the patient's body. B, With a 16-slice, multirow detector, the chest, abdomen, and pelvis can be imaged with five circular passes, easily obtained during a single breath hold. The thin slices offered by the 16-slice detector offer much greater detail of internal structures.

Figure 2-14. A, Three-dimensional (3D) colored reconstruction of the kidneys, ureters, and bladder from computed tomography urogram. B, Coronal reconstruction in a patient with a clear cell renal cell carcinoma in a complex renal cystic mass and enhancing mural nodule. C, 3D reconstruction of the same patient with slight posterior rotation.

Urologists often request a CT evaluation of the abdomen and pelvis. An abdominal CT starts at the diaphragm and ends at the iliac crest. If the pelvis is to be imaged, a separate request is usually required. The pelvic CT begins at the iliac crest and terminates at the pubis symphysis. Intravenous contrast may be required for better delineation of soft tissue. Oral contrast is not commonly used in urology but may be helpful in certain patients to differentiate bowel from lymph nodes, scar, or tumor (Fig. 2-15).

Hounsfield Units

A single CT image generated by the scanner is divided into many tiny blocks of different shades of black and white called pixels. The

actual gray scale of each pixel on a CT depends on the amount of radiation absorbed at that point, which is termed an attenuation value. Attenuation values are expressed in Hounsfield units (HU). The HU scale, or attenuation value, is based on a reference scale in which air is assigned a value of -1000 HU and dense bone is assigned the value of $+1000$ HU. Water is assigned 0 HU.

Urolithiasis

Patients coming to the emergency department with abdominal pain or renal colic are frequently evaluated with CT imaging. The use of unenhanced CT imaging to identify urolithiasis was first reported in 1995 (Smith et al, 1995) and has now become the standard

Figure 2-15. Computed tomography of the abdomen and pelvis demonstrating normal genitourinary anatomy. A, The adrenal glands are indicated with *arrows*. The upper poles of the right and left kidneys are indicated with rk and lk, respectively. a, aorta; li, liver; p, pancreas; s, spleen; v, inferior vena cava. B, Scan through the upper pole of the kidneys. The left adrenal gland is indicated with an *arrow*. a, aorta; c, colon; d, duodenum; li, liver; lk, left kidney; p, pancreas; rk, right kidney; v, inferior vena cava. C, Scan through the hilum of the kidneys. The main renal veins are indicated with *solid arrows*, and the right main renal artery is indicated with an *open arrow*. a, aorta; c, colon; d, duodenum; li, liver; lk, left kidney; p, pancreas; rk, right kidney; v, inferior vena cava. D, Scan through the hilum of the kidneys slightly caudal to C. The left main renal vein is indicated with a *solid straight arrow*, and the left main renal artery is indicated with an *open arrow*. The hepatic flexure of the colon is indicated with a *curved arrow*. a, aorta; c, colon; d, duodenum; li, liver; lk, left kidney; p, pancreas; rk, right kidney; v, inferior vena cava. E, Scan through the mid to lower polar region of the kidneys. a, aorta; ac, ascending colon; d, duodenum; dc, descending colon; lk, left kidney; p, pancreas; rk, right kidney; rp, renal pelvis; v, inferior vena cava. F, CT scan obtained below the kidneys reveals filling of the upper ureters (*arrows*). The wall of the normal ureter is usually paper thin or not visible on CT. a, aorta; ac, ascending colon; dc, descending colon; v, inferior vena cava.

Figure 2-15, cont'd G, Contrast filling of the midureters (arrows) on a scan obtained at the level of the iliac crest and below the aortic bifurcation. ac, ascending colon; dc, descending colon; la, left common iliac artery; ra, right common iliac artery; v, inferior vena cava. H, The distal ureters (arrows) course medial to the iliac vessels on a scan obtained below the promontory of the sacrum. b, urinary bladder; la, left external iliac artery; lv, left external iliac vein; ra, right external iliac artery; rv, right external iliac vein. I, Scan through the roof of the acetabulum reveals distal ureters (solid arrows) near the ureterovesical junction. The bladder (b) is filled with urine and partially opacified with contrast material. The normal seminal vesicle (open arrows) usually has a paired bow-tie structure with slightly lobulated contour. a, right external iliac artery; r, rectum; v, right external iliac vein. J, Scan at the level of the pubic symphysis (large open arrow) reveals the prostate gland (solid arrow). a, right external iliac artery; m, obturator internus muscle; r, rectum; v, right external iliac vein; small open arrows, seminal vesicle.

diagnostic tool to evaluate renal colic. It offers the advantage over IVU of avoiding contrast and being able to diagnose other abdominal abnormalities that can also cause abdominal pain. MDCT can readily diagnose radiolucent stones which may not have been seen on IVU, as well as small stones even in the distal ureter (Federle et al, 1981). With the exception of some indinavir stones, all renal and ureteral stones can be detected on helical CT scan (Schwartz et al, 1999). In the workup of urolithiasis, the unenhanced CT has a sensitivity ranging between 96% and 100% and specificity ranging between 92% and 100% (Memarsadeghi et al, 2005). Stones in the distal ureter can be difficult to differentiate from pelvic calcifications. In these cases, the urologist needs to look for other signs of obstruction which indicate the presence of a stone, including ureteral dilation, inflammatory changes in the perinephric fat, hydronephrosis, and a soft tissue rim surrounding the calcification within the ureter. The soft tissue rim around a stone represents irritation and edema in the ureteral wall (Heneghan et al, 1997; Dalrymple et al, 2000) (Fig. 2-16).

Stone patients are frequently subjected to radiation exposure as part of diagnosis, treatment, and follow-up. Increasing awareness of the potential long-term adverse effects of radiation exposure has encouraged urologists and radiologists to discover means to decrease the amount of radiation exposure. The low-dose, unenhanced helical CT scan is gaining increasing popularity for initial diagnosis of renal colic suspected to be due to urolithiasis and for follow-up

in stone patients. Using low-dose CT protocols, the specificity and sensitivity of unenhanced low-dose helical CT scan is approximately 96% and 97%, respectively. Low-dose techniques offer a 99% positive predictive value and a 90% negative predictive value for urolithiasis. The end result is a 50% to 75% decrease in the patient's total radiation exposure for each CT obtained (Liu et al, 2000; Hamm et al, 2002; Kalra et al, 2005).

Cystic and Solid Renal Masses

The frequent CT imaging of patients in the emergency department has resulted in an increase in the detection of incidental renal masses. Using CT imaging the mass can be characterized as a simple or complex cyst, or a solid mass. Based on the HU attenuation scale, we would expect simple cysts to have HU near zero (Fig. 2-17).

When the unenhanced CT images of a renal mass are compared to the enhanced images obtained in the cortical medullary or nephrogenic phase, an increase in HU (measured in the area of the renal mass) by 15 to 20 HU confirms the presence of a solid enhancing mass, which is usually renal cancer. Pseudoenhancement is maximal when small (≤ 1.5 cm) intrarenal cysts are scanned during maximal levels of renal parenchymal enhancement. The magnitude of this effect varies with scanner type but may be large enough to prevent accurate lesion characterization, despite use of a thin-section helical CT data acquisition technique (Birnbau

Figure 2-16. Computed tomography of the abdomen and pelvis in patient with an obstructing ureteral stone at the level of the ureterovesical junction (UVJ). A, Level of the left upper pole. Mild renal enlargement, caliectasis, and perinephric stranding are apparent. B, Level of the left renal hilum. Left pyelectasis with a dependent stone, mild peripelvic and perinephric stranding, and a retroaortic left renal vein are shown. C, Level of the left lower pole. Left caliectasis, proximal ureterectasis, and mild periureteral stranding are present. D, Level of the aortic bifurcation. The dilated left ureter (*arrow*) has lower attenuation than do nearby vessels. E, Level of the upper portion of the sacrum. A dilated left ureter (*arrow*) crosses anteromedial to the common iliac artery. F, Level of the midsacrum. A dilated left ureter (*arrow*) is accompanied by periureteral stranding. G, Level of the top of the acetabulum showing a dilated pelvic portion of the left ureter (*arrow*). H, Level of the UVJ. The impacted stone with a “cuff” or “tissue rim” sign that represents the edematous wall of the ureter. (From Talner LB, O’Reilly PH, Wasserman NF. Specific causes of obstruction. In: Pollack HM, McClennan BL, Dyer R, et al, editors. Clinical urography. 2nd ed. Philadelphia: Saunders; 2000.)

Figure 2-17. Renal computed tomography (CT) demonstrating normal nephrogenic progression. A, Unenhanced CT scan obtained at the level of the renal hilum shows right (R) and left (L) kidneys of CT attenuation values slightly less than those of the liver (H) and pancreas (P). A, abdominal aorta; M, psoas muscle; S, spleen; V, inferior vena cava. B, Enhanced CT scan obtained during a cortical nephrographic phase, generally 25 to 80 seconds after contrast medium injection, reveals increased enhancement of the renal cortex (C) relative to the medulla (M). The main renal artery is indicated with *solid arrows* bilaterally. Main renal veins (*open arrows*) are less opacified with respect to the aorta (A) and arteries. D, duodenum; P, pancreas; V, inferior vena cava. C, CT scan obtained during the homogeneous nephrographic phase, generally between 85 and 120 seconds after contrast medium administration, reveals a homogeneous, uniform, increased attenuation of the renal parenchyma. The wall of the normal renal pelvis (RP) is paper thin or not visible on the CT scan. A, abdominal aorta; V, inferior vena cava. D, CT scan obtained during the excretory phase shows contrast medium in the renal pelvis (RP) bilaterally; this starts to appear approximately 3 minutes after contrast medium administration.

et al, 2002). The presence of fat, which should enhance less than 10 HU, is diagnostic for angiomyolipoma. A hyperdense cyst shows no change in density between the postcontrast and delayed phase images (Fig. 2-18).

Complex cystic masses are usually characterized based on the Bosniak classification system. The most important criteria used to differentiate a lesion that should be considered for surgery versus a nonsurgical lesion is the presence or absence of tissue vascularity or enhancement. Bosniak category I, II, and IIF lesions do not enhance to any measurable degree. Category I lesions are simple cysts and considered to be benign. Category II lesions are more complicated and may have calcifications, high attenuation fluid, and several thin septae. Category III lesions are more complex, have small areas of calcification, and may also have irregular walls or septate where there is measurable enhancement. Cystic lesions discovered on CT scan that are difficult to categorize as either II or III are categorized as IIF. Bosniak III lesions have been reported to be malignant renal cell carcinoma in 60% of cases and require close follow-up or surgical extirpation. Bosniak category IV lesions are cystic masses that meet all the criteria of category

III, but also have enhancing soft tissue components adjacent to or independent of the wall or septum of the cyst; they have been reported to be malignant renal cell carcinoma in 100% of cases (Bosniak, 1997; Curry et al, 2000; Israel and Bosniak, 2005).

Hematuria

The CTU is one of the most common studies ordered for the workup of gross or microscopic hematuria. With MDCT it is possible to perform a comprehensive evaluation of the patient with one single examination (Chai et al, 2001). The study images the abdomen and pelvis and typically includes four different phases. The first scan is an unenhanced CT to distinguish between different masses that can be present in the kidney and uncover kidney stones that would later be obscured by the excretion of contrast into the renal collecting system. At 30 to 70 seconds after contrast injection, the corticomedullary phase is captured with another pass through the MDCT, helping to define vasculature and perfusion. The nephrogenic phase occurs between 90 to 180 seconds after injection of contrast

Figure 2-18. Small renal cell carcinoma in the infrahilar lip of the right kidney is not easily seen on unenhanced image (A). On corticomedullary phase image (B), the lesion is subtly visible as a hyperenhancing focus within the renal medulla. On nephrographic (C) and pyelographic phase (D) images, the full extent of the lesion (arrow) within the medulla and cortex is depicted. (From Brink JA, Siegel CL. *Computed tomography of the upper urinary tract*. In: Pollack HM, McClenan BL, Dyer R, et al, editors. *Clinical urography*. 2nd ed. Philadelphia: Saunders; 2000.)

and, when compared to the unenhanced images, allows sensitive detection and characterization of renal masses. The final phase is the excretory phase, imaged approximately 3 to 5 minutes after injection of contrast. This phase allows complete filling of the collecting system and usually allows visualization of the ureter (Joudi et al, 2006) (see Fig. 2-18).

CTU has been shown to be sensitive in detecting upper tract urothelial cancers. In one series of 57 patients with hematuria, 38 were found to have urothelial carcinoma. CT urography detected 37 of 38 urothelial cancers for a sensitivity of 97%, compared to retrograde pyelogram which detected 31 of 38 lesions and had a sensitivity of 82%. Approximately 90% of malignant upper tract lesions can be detected with CT urography (McCarthy and Cowan, 2002; Lang et al, 2003; Caoili et al, 2005). CT urography is not as sensitive as cystoscopy for the detection of urothelial tumors in the bladder. Only large bladder tumors are visualized with CT imaging studies as filling defects in the lumen of the bladder. Carcinoma in situ cannot be visualized on CT scanning, and therefore cystoscopy is still an important part of a comprehensive hematuria workup.

KEY POINTS: CT IMAGING

- The CTU is an excellent imaging choice to evaluate the kidney, upper tract collecting system, and ureter.
- The CTU is highly sensitive and specific for upper tract urothelial carcinoma.
- A renal mass in the kidney seen on CTU that enhances more than 15 to 20 HU is most likely a renal cancer.
- With the exception of indinavir stones, all urinary stones are visible on unenhanced CT of the abdomen and pelvis.

MAGNETIC RESONANCE IMAGING

CT imaging remains the mainstay of urologic cross-sectional body imaging; however, MRI is increasingly being applied to the genitourinary system. With constant improvements in technology, MRI is gradually narrowing the overall resolution quality gap between the two techniques. A significant advantage of MRI is the excellent

signal contrast resolution of soft tissue, without the need for IV contrast in many situations.

To obtain MR images, the patient is placed on a gantry that passes through the bore of the magnet. When exposed to a magnet field of sufficient strength, the free water protons in the patient orient themselves along the magnetic field's z-axis. This is the head-to-toe axis, straight through the bore of the magnet. An RF antenna or "coil" is placed over the body part to be imaged. It is the coil that transmits the RF pulses through the patient. When the RF pulse stops, protons release their energy, which is detected and processed to obtain the MR image. Currently, some coils can transmit and receive a signal, which is referred to as dual channel RF. An MR sequence exploits the body's different tissue characteristics and the particular manner that each type of tissue absorbs and then releases this energy.

Weighting of the image depends on how the energy is imparted through the physics of the pulse sequence and whether the energy is released quickly or slowly. Images are described as being T1 or T2 weighted. The T1-weighted images are generated by the time required to return to equilibrium in the z-axis. The T2-weighted images are generated by the time to return to equilibrium in the xy-axis. On T1-weighted MR images, fluid has a low SI and appears dark. T2-weighted MR images have a high SI and appear bright. In the kidney this translates into the cortex having a higher SI or being brighter than the medulla, which gives off a lower signal and is darker.

MRI has significant advantages over other imaging modalities. First, and most importantly, no risks are associated with secondary malignancies from radiation exposure (Berrington de González and Darby, 2004). It is the modality of choice in patients who are pregnant, suffer from renal insufficiency, and/or have an iodine contrast allergy.

The contrast agents in MRI are noniodinated compounds. Iodinated compounds as used in CT imaging function by absorbing x-rays. Gd-based contrast agents function on MRI secondary to shortening the relaxation times of water. This results in an increase in SI (enhancement), most commonly assessed in a T1 sequence. Gd is a toxic heavy metal that is chelated to prevent cellular absorption and any associated toxicities (Lin and Brown, 2007). The dose of Gd is nontoxic for almost all patients except ones with severe renal insufficiency. NSF occurs in patients with acute or chronic renal insufficiency with a GFR less than 30 mL/min/1.73 m² (see Contrast Media). Gd is deposited in skin and muscle as an insoluble precipitate that leads to the systemic fibrosis (Grobner, 2006). In response, the FDA has issued warnings regarding the association between NSF and Gd-based contrast agents because no effective treatment is available (U.S. Food and Drug Administration, 2006). The current guidelines are available at the FDA.gov official website (U.S. Food and Drug Administration, 2010).

Adrenal Magnetic Resonance Imaging

One of the key differences between MRI and other imaging modalities is its ability to characterize soft tissues without the use of IV contrast. In the adrenal gland, minute quantities of lipids can help differentiate between malignancies or benign adenomas. Most adrenal masses are identified incidentally and are nonfunctioning.

Adrenal adenomas are usually less than 3 cm in size and nonfunctional (Boland et al, 2008). Adrenal adenomas have a high lipid content (74%), which makes them more readily differentiated from malignant processes (Dunnick and Korobkin, 2002).

Inversion-recovery imaging, chemical shift imaging (CSI), and fat saturation imaging are three approaches to assess lipid content on masses. These approaches use the differences in the behavior of fat protons and water protons within the magnetic field. CSI is the most commonly used technique for urologic patients.

Adrenal Adenoma

Adrenal adenomas are characterized by assessing the lipid content within cells. CSI uses the difference in the behavior of water protons

(H₂O) versus fat protons (-CH₂-). The oxygen atom in water pulls on the electron cloud surrounding the hydrogen atom, whereas the carbon atom in fat is less electronegative and has a decreased effect on the hydrogen electron cloud (Pokharel et al, 2013). This difference in the magnetic field (shielding) for these two types of protons is the precessional frequencies or the chemical shift (Pokharel et al, 2013).

CSI obtains images "in-phase" (IP) and "out-of-phase" (OP) with regard to the water and fat protons. The signals detected for a given voxel can be additive or cancelled out. The IP imaging refers to the contribution of both fat and water, or additive to the signal at a given voxel. This occurs when the echo time (TE) is set to align the fat and water protons.

In the OP imaging, the TE is set to cancel the signals obtained, thus the subtraction of the protons results in a decrease, or cancelling, in signal at that given voxel and produces a lower SI if both fat and water are present.

The next step is to compare the two data sets (IP and OP) obtained to determine if there is a loss of signal (decrease) on the OP images, which is indicative of intracytoplasmic fat (Fig. 2-19). If there is no change between the two data sets, then there is a lower probability that fat is present within the mass. This was initially determined on a qualitative basis by visually comparing signal intensities between the two sequences (Korobkin et al, 1996). The loss of signal on CSI is 92% sensitive and has a limited specificity of 17% for adrenal adenoma (Boland et al, 2008).

Other investigators have attempted to determine SI index by quantitatively comparing the IP and OP images. Nakamura reported that using a 5% SI yielded an accuracy of 100% (3 tesla) in determining if intracytoplasmic lipid was present and thus a diagnosis of an adenoma (Nakamura et al, 2012). Although there are currently no set thresholds, cutoff ranges are reported to be between 1.7% and 20% (Nakamura et al, 2012). The limited specificity reported by the qualitative approach (17%) was increased to 100% specificity using quantitative SI index (Boland et al, 2008).

$$\text{SI index (\%)} = (\text{SI in phase} - \text{SI out of phase}) / \text{SI in phase} \times 100$$

In some clinical situations, lipid poor adenomas (10% to 30% incidence) can result in an indeterminate study (Elsayes et al, 2004). The typical washout of an adrenal cortical carcinoma is slow. Therefore an enhanced CT with washout may be a better study to differentiate lipid-poor adrenal adenomas from other adrenal masses (Park et al, 2007).

Adrenal Cortical Carcinoma

An adrenal cortical carcinoma (ACC) diagnosis is usually made using a combination of clinical factors and imaging characteristics (Fig. 2-20). In a review by Ng and Libertino (2003), ACC is hormonally active in 62% of cases. The incidence of ACC is related to size, and adrenal lesions equal to or less than 4 cm represented 2% of all ACC diagnosed. The incidence of ACC increased to 6% for lesions 4 to 6 cm and to 25% for lesions greater than 6 cm (Mansmann et al, 2004). T2- and T1-weighted images with Gd usually are heterogeneous with a high SI and a heterogeneous enhancement, respectively. CSI exhibits a low signal (Bharwani et al, 2011). ACC is also associated with local vascular thrombosis, which can be detected on MRI (Mezhir et al, 2008). ACC has an increased metabolic activity and can be visualized on FDG-PET imaging, and this can differentiate ACC from adenomas with 100% sensitivity and 88% specificity (Groussin et al, 2009).

Myelolipoma

Myelolipoma is a benign adrenal mass that consists of mature fatty tissues and bone marrow elements. Myelolipoma occurs in approximately 6.5% of patients with incidentally detected adrenal masses (Song et al, 2008). The complicating issue with myelolipomas is that the size of the mass can be greater than 4 cm, and this carries significant overlap with malignant adrenal lesions (Meyer

Figure 2-19. A 45-year-old man underwent 1.5-tesla magnetic resonance imaging with chemical shift imaging, which was consistent with left adrenal adenoma (red arrow). A, In-phase T1-weighted image demonstrates left adrenal mass with signal isointense to muscle. B, Out-of-phase T1-weighted imaging shows dropout of signal in left adrenal mass relative to the in-phase imaging. C, Single-shot, T2-weighted spin echo image reveals left adrenal nodule with low signal intensity.

Figure 2-20. A 65-year-old woman with left side heterogeneous enhancing suprarenal lesion (adrenal cortical carcinoma) with select images from a 1.5-tesla abdominal magnetic resonance image. A, Moderately weighted T2 STIR (short-tau inversion recovery) images with a hyperintense signal (red arrows). B, Heavily weighted T2 single-shot, fast spin echo isointense signal. These findings are all dependent on the degree of T2 weighting.

and Behrend, 2005). On MRI a myelolipoma has a high SI on T1-weighted imaging, suppressed signal on frequency selective fat suppression, and an India ink artifact (Taffel et al, 2012) (Fig. 2-21). India ink artifact appears as a dark line around the lesion and/or organs and is the result of a voxel containing both fat and water on chemical shift OP images.

Metastasis

An adrenal mass is considered to be metastatic in the setting of a known primary malignancy. The MRI findings are consistent with a large, irregular, heterogeneous mass with occasional necrosis present on imaging. Metastases have a high signal on T2-weighted

Figure 2-21. A 44-year-old man, with prior abdominal ultrasonography detecting an indeterminate renal mass, underwent 1.5-tesla magnetic resonance imaging with chemical shift imaging, which was consistent with left adrenal myelolipoma (red arrow). A, T2 single-shot spin echo demonstrates a large left adrenal mass with signal isointense to abdominal fat. B, T1 in-phase imaging demonstrates a left adrenal mass with signal similar to the abdominal fat. C, T1 out-of-phase imaging shows no drop of signal compared with in-phase imaging. D, T1 fat-suppressed precontrast imaging shows loss of signal within the mass consistent with gross fat.

images secondary to higher fluid content, compared with adrenal adenoma (Sahdev et al, 2010). Gd enhancement on T1-weighted images demonstrates heterogeneous enhancement with a delayed peak enhancement (65 seconds) when compared with adrenal adenomas (40 seconds). Using a time to peak enhancement cutoff of 53 seconds or greater resulted in 87.5% sensitivity and 80% specificity in characterizing metastatic adrenal lesions (Inan et al, 2008).

Patients with primary lesions that are known to contain intracytoplasmic fat may require additional imaging to better differentiate an adrenal gland lesion. The metastatic sites often carry the same histologic features as the primary tumor. This can result in a false-positive for adrenal adenomas if the primary contains intracytoplasmic lipid content (CSI positive) (Krebs and Wagner, 1998) (Fig. 2-22). This has been reported in liposarcoma, renal cell carcinoma, and hepatocellular carcinoma (Krebs and Wagner, 1998; Sydow et al, 2006).

Pheochromocytoma was traditionally considered to be diagnostic if on T2-weighted images the lesion demonstrated an increased SI (Fig. 2-23). However, Varghese and colleagues (1997) reported that 35% of pheochromocytomas demonstrated low T2 signal,

contrary to conventional teaching. Pheochromocytoma, ACC, and metastatic lesions to the adrenal gland can exhibit a hyperintense SI or appear bright on T2-weighted images. It is important to understand that the SI can vary because of degree of weighting of the T2 signal and not have the traditional findings of being bright on T2-weighted images (see Figs. 2-20, 2-22, and 2-23). The pheochromocytoma can be characterized on MRI without the need for contrast enhancement, avoiding a potential hypertensive crisis that has been associated with iodine contrast media in these patients (Raisanen et al, 1984).

Lymphoma, neuroblastoma, ganglioneuroma, hemangioma, and granulomatous diseases of the adrenal gland have an intermediate SI index on CSI and other imaging findings (Table 2-3).

Adrenal hematomas have variable imaging characteristics on MRI because of changes in the hematoma from initial acute bleeding to breakdown products of red blood cells with deposition of hemosiderin within the hematoma. This progresses from an isointense to hypointense signal on T1 and low signal on T2 to hyperintense on T1 fat-suppressed sequences and T2 sequences at 1 to 7 weeks. A low signal rim is present on both T1 and T2 sequences because of hemosiderin deposits (Taffel et al, 2012).

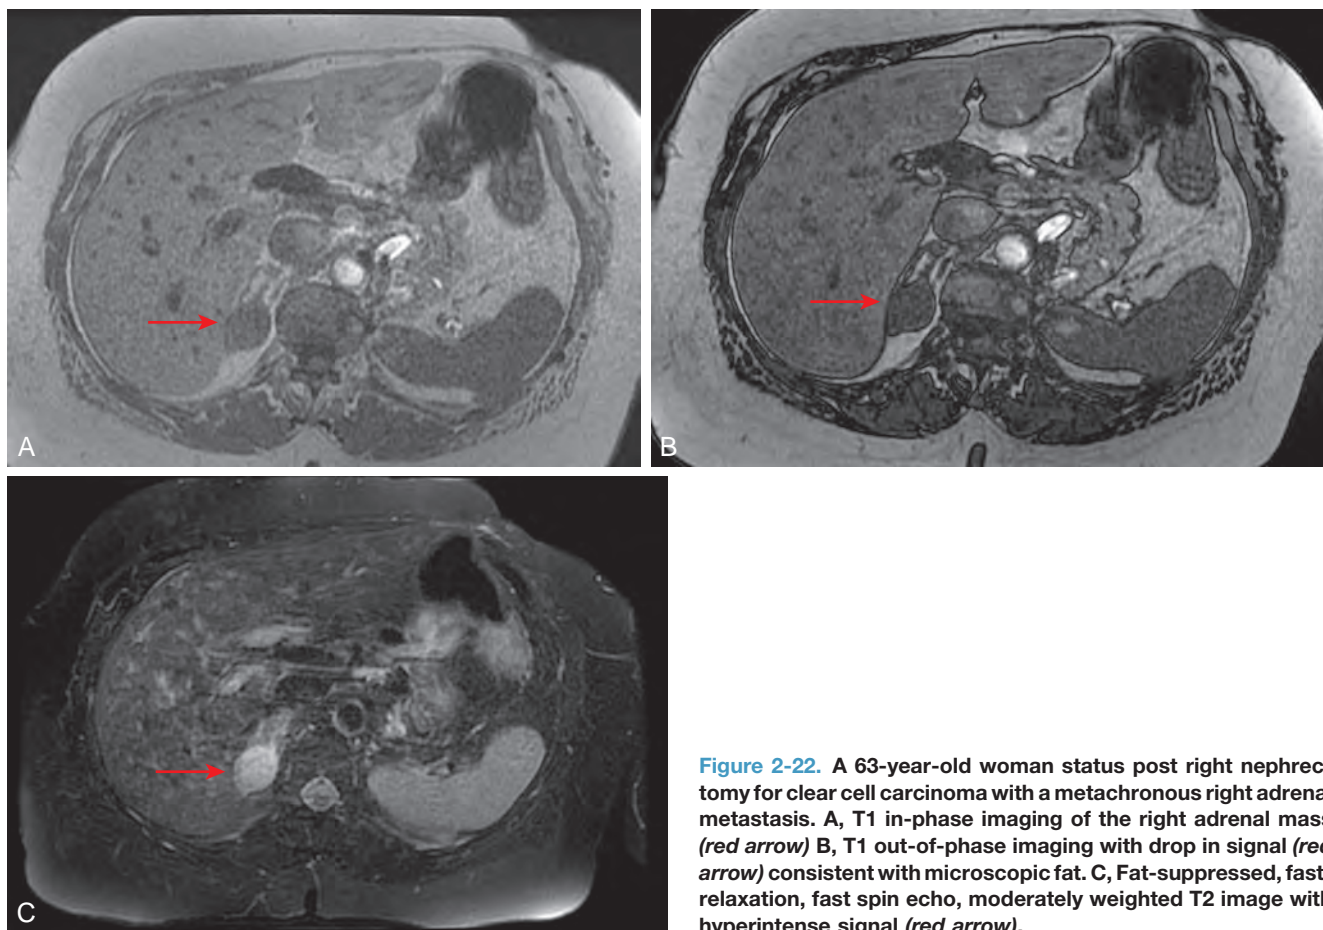

Figure 2-22. A 63-year-old woman status post right nephrectomy for clear cell carcinoma with a metachronous right adrenal metastasis. A, T1 in-phase imaging of the right adrenal mass (red arrow) B, T1 out-of-phase imaging with drop in signal (red arrow) consistent with microscopic fat. C, Fat-suppressed, fast-relaxation, fast spin echo, moderately weighted T2 image with hyperintense signal (red arrow).

Renal Magnetic Resonance Imaging

Simple cysts have similar characteristics on ultrasonography, CT, and MRI. Complex cysts can also be differentiated or characterized using MRI. Hemorrhage within the cyst results in a high signal on T1-weighted images because of the paramagnetic effects of blood breakdown products (hemosiderin) (Roubidoux, 1994) (Fig. 2-24).

Proteinaceous contents within a cyst can also demonstrate high signal on T1-weighted images. Chronic hemorrhage results in a black ring along the cyst wall on T2-weighted images. For benign, complex cysts there should be no enhancement of any component of the cysts (Israel et al, 2004).

Because MRI is insensitive to calcifications, any calcifications present on the lining of a complex cyst are not well visualized. When evaluating independent risk factors for renal cell carcinoma, enhancement of the cyst wall had higher sensitivity and specificity than calcifications on the cyst wall. Calcifications can cause artifacts that may decrease the ability to appreciate enhancement of small nodules within the wall of a complex cyst on CT imaging. MRI has the advantage of not being influenced by calcifications within the wall of a complex cyst. Therefore MRI is more likely to detect enhancement of a renal cell carcinoma in the wall of a complex cyst, compared with CT imaging when mural calcifications are present (Israel and Bosniak, 2003).

MRI offers a distinct advantage over CT imaging with regard to detection and evaluation of the pseudocapsule that appears on T1- and T2-weighted images as a low signal surrounding the lesion. The lack of pseudocapsule surrounding a renal mass had an accuracy of 91% in predicting pT3a disease (Roy et al, 2005).

MRI allows differentiation of different subtypes of renal cell carcinoma by using a multiparametric approach. These sequences can include: T1-weighted images; multiplanar T2-weighted sequences with and without fat suppression; dynamic contrast enhanced

(DCE) sequences with arterial, corticomedullary, and nephrogenic and excretory phases; diffusion-weighted images (DWI) with corresponding apparent diffusion coefficient (ADC) maps; and CSI. Using these unique features we are better able to differentiate the subtypes of renal masses compared with CT imaging.

Renal cell carcinoma clear cell type (cRCC) is the most common type of renal cell carcinoma. It is characterized by a heterogeneous high signal on T2-weighted sequences because of the presence of hemorrhage, necrosis, and/or cysts (see Fig. 2-24). Papillary renal cell carcinoma (pRCC), when compared to cRCC, exhibits a homogeneous lower SI on T2-weighted images, which is secondary to hemosiderin deposition (histiocytes) within the tumor (Fig. 2-25). Hemorrhagic cysts with an enhancing peripheral wall growth and/or a solid hypoenhancing mass with low SI on T2-weighted images resulted in 80% sensitivity and 94% specificity in differentiating pRCC from other types of RCCs (Fig. 2-26) (Pedrosa et al, 2008).

Like adrenal MR imaging, CSI can detect intracytoplasmic lipids and aid in the differentiation of cRCC from other RCC subtypes (see Fig. 2-24). Microscopic intracytoplasmic lipids have been found in 59% of clear cell carcinomas (Outwater et al, 1997). Karlo and colleagues (2013) reported that once angiomyolipoma (AML) has been ruled out using standard MRI techniques (Fig. 2-27) in which macroscopic fat has been detected, CSI sequences with a 25% decrease in SI can be considered diagnostic for cRCC from other renal tumors. Pedrosa and colleagues (2008) reported the sensitivity and specificity of CSI for cRCC was 42% and 100%, respectively. There are rare cases of RCC with macroscopic fat; however, if calcifications are also present, this would favor the diagnosis of RCC over AML (Wasser et al, 2013).

Gd-enhanced T1-weighted images with a relative SI increase of 15% is considered to be positive enhancement, which results in a 100% sensitivity in differentiation of cysts from renal cell carcinoma

A, Heavily weighted T2 single-shot fast spin echo with an isointense signal (not bright). B, Moderately weighted T2 fat-suppressed, fast-recovery, fast spin echo with hyperintense signal (bright). C, T1-weighted precontrast image. D, T1-weighted postcontrast image with marked early enhancement.

TABLE 2-3 Morphologic and Imaging Characteristics of Incidental Adrenal Lesions

IAL	SIZE (cm)	SHAPE	TEXTURE	UNENHANCED CT ATTENUATION (HU)	15-MINUTE CT WASHOUT (%)	MRI SIGNAL CHARACTERISTICS	NUCLEAR MEDICINE CHARACTERISTICS
Adrenal metastasis	Variable	Variable	Heterogeneous when larger	>10	RPW <40	High T2 signal	Positive on PET images
Adrenal cortical carcinoma	>4	Variable	Variable	>10	RPW <40	Intermediate to high T2 signal	Positive on PET images
Pheochromocytoma	Variable	Variable	Variable	>10, rarely <10	RPW <40	High T2 signal	Positive on MIBG
Cyst	Variable	Smooth, round	Smooth	<10	Does not enhance	High T2 signal	Negative
Adenoma	1-4	Smooth, round	Homogeneous	<10 in 70%	RPW >40; APW >60	SI dropoff on OP images	Variable on PET images
Myelolipoma	1-5	Smooth, round	Variable with macroscopic fat	<0, often ≤50	No data	High T1 signal, India ink, variable SI dropoff on OP images	Negative on PET images
Lymphoma	Variable	Variable	Variable	>10	RPW <40	Intermediate SI	Variable positivity on PET images
Hematoma	Variable	Smooth	Variable	>10, sometimes >50	No data	Variable signal	Negative
Neuroblastoma	Variable	Variable	Smooth, round	>10	RPW <40	Variable if necrotic	Positive
Ganglioneuroma	Variable	Variable	Variable	>10	No data	Usually intermediate SI	Usually negative
Hemangioma	Variable	Variable	Variable	>10	No data	Usually intermediate SI	Usually negative
Granulomatous	1-5	Smooth	Usually homogeneous	>10	No data	Usually intermediate SI	Positive on PET images if active

APW, absolute percentage washout; CT, computed tomography; HU, Hounsfield unit; IAL, incidental adrenal lesion; MIBG, m-iodobenzylguanidine; MRI, magnetic resonance imaging; OP, out-of-phase; PET, positron emission tomography; RPW, relative percentage washout; SI, signal intensity.

Figure 2-24. A 31-year-old woman, after left extracorporeal shock wave lithotripsy with a subcapsular hematoma and right side pathology confirmed 3.5-cm clear cell carcinoma, underwent 1.5-tesla magnetic resonance imaging of the abdomen. A, T1-weighted in-phase imaging of a right renal nodule with mild heterogeneity (*red arrow*) but primarily isointense signal intensity (SI). Left kidney subcapsular hematoma with a rim of high SI (*blue arrow*). B, T1-weighted out-of-phase image shows diffuse signal dropout within the renal nodule consistent with microscopic fat. C, T1-weighted fat-suppressed precontrast image with a low SI of the right renal nodule (*red arrow*) and high SI of the left subcapsular hematoma (*blue arrow*). Blood is high SI on precontrast T1-weighted images. D, T1 fat-suppressed postcontrast images of the right renal nodule with avid heterogeneous enhancement. Unenhancing left subcapsular hematoma (*blue arrow*). E, Diffusion-weighted imaging b-1000 shows high SI throughout the right renal nodule.

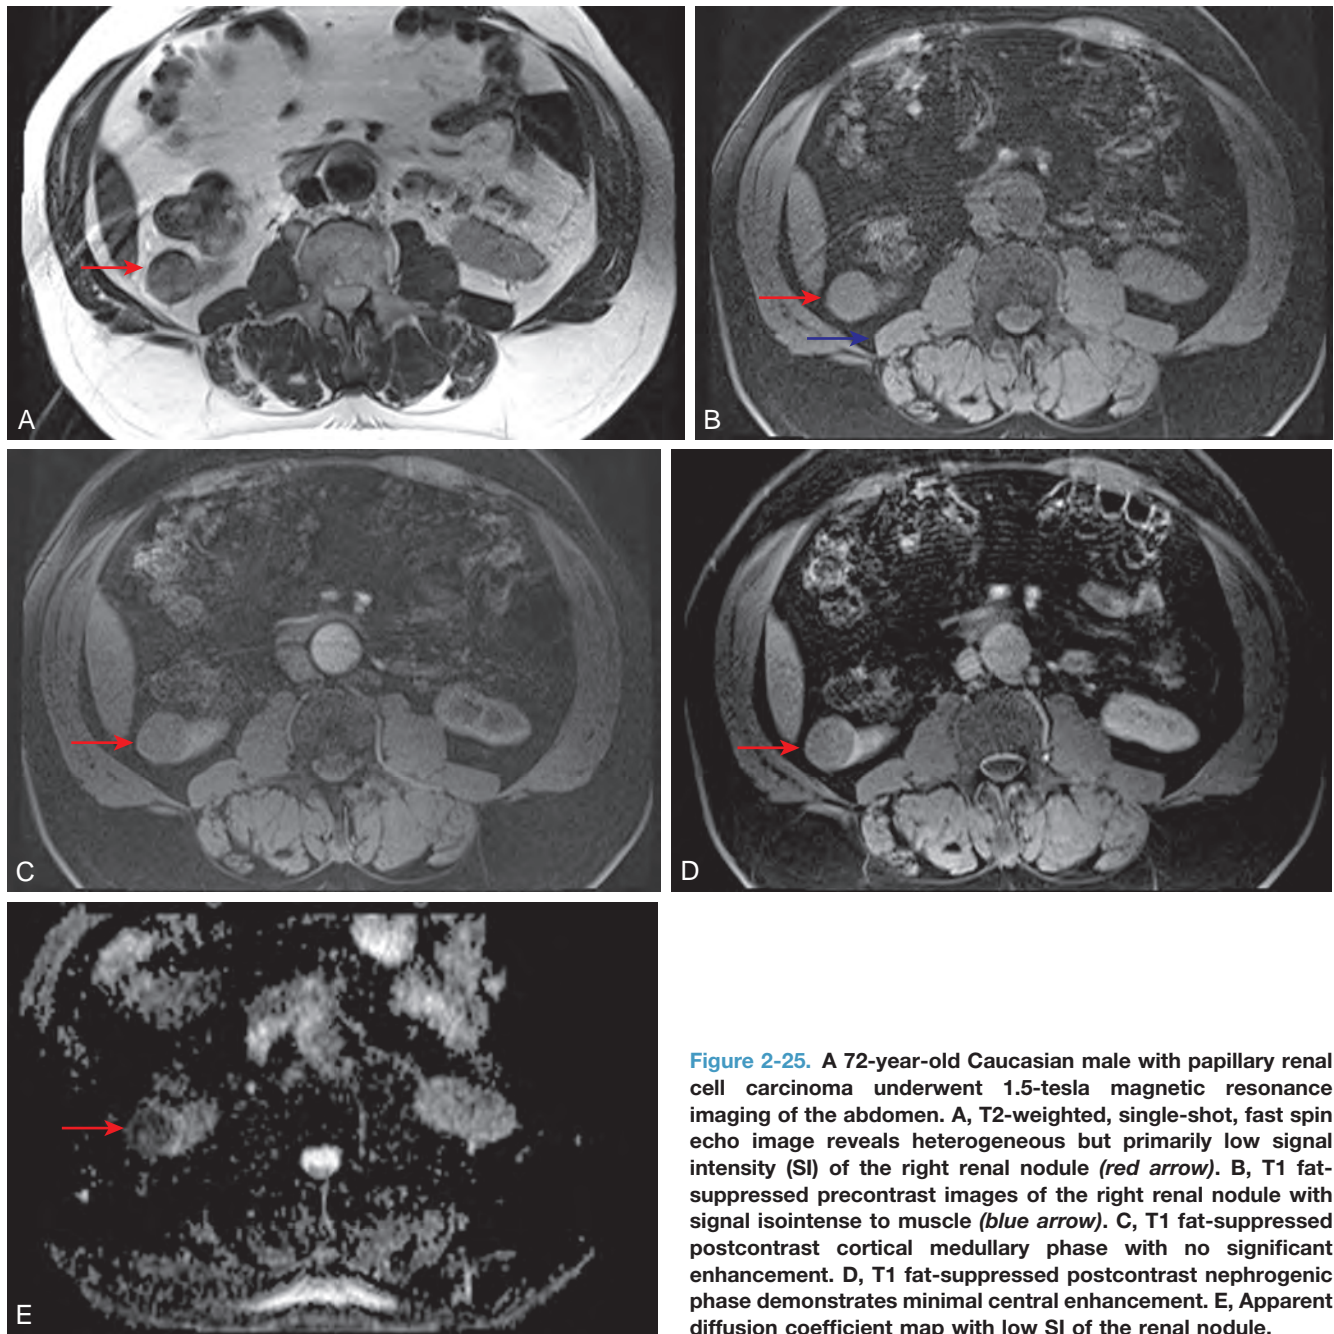

Figure 2-25. A 72-year-old Caucasian male with papillary renal cell carcinoma underwent 1.5-tesla magnetic resonance imaging of the abdomen. A, T2-weighted, single-shot, fast spin echo image reveals heterogeneous but primarily low signal intensity (SI) of the right renal nodule (*red arrow*). B, T1 fat-suppressed precontrast images of the right renal nodule with signal isointense to muscle (*blue arrow*). C, T1 fat-suppressed postcontrast cortical medullary phase with no significant enhancement. D, T1 fat-suppressed postcontrast nephrogenic phase demonstrates minimal central enhancement. E, Apparent diffusion coefficient map with low SI of the renal nodule.

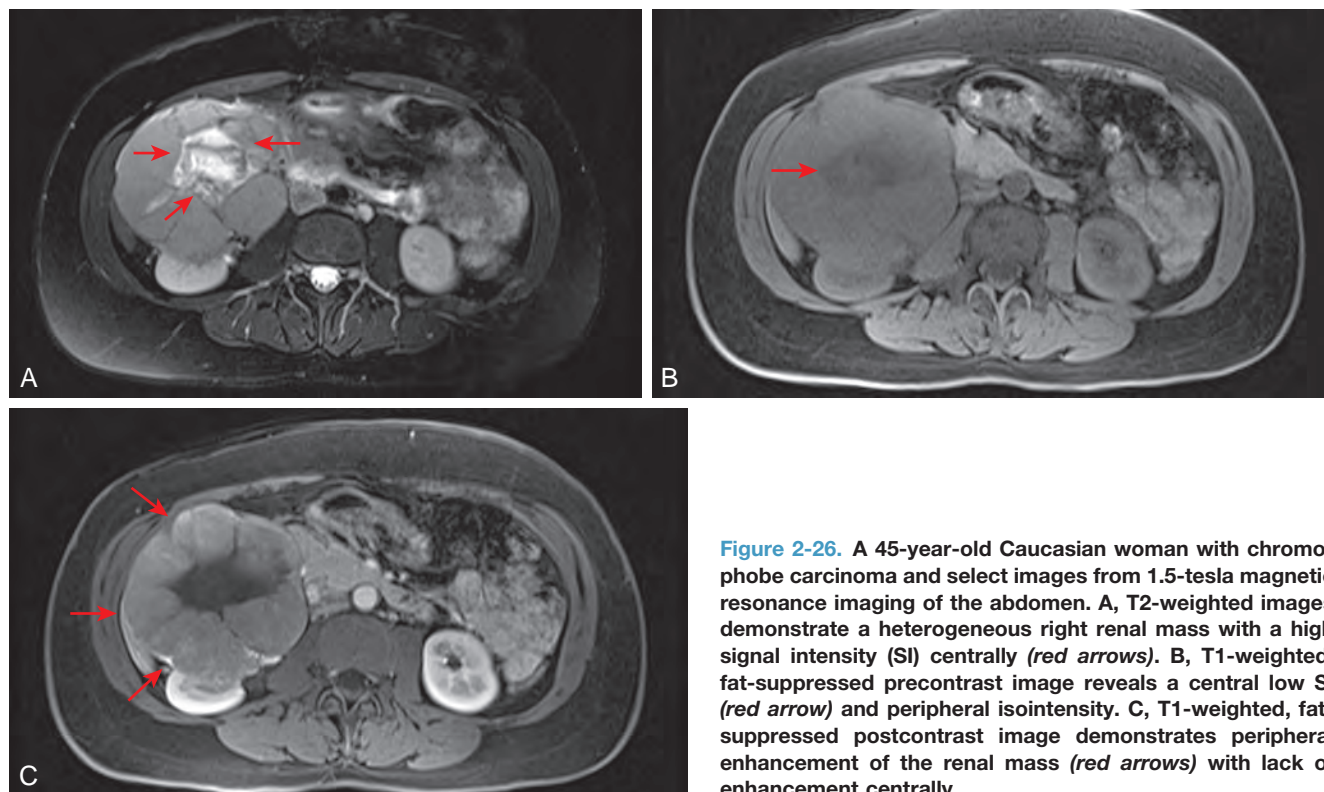

Figure 2-26. A 45-year-old Caucasian woman with chromophobe carcinoma and select images from 1.5-tesla magnetic resonance imaging of the abdomen. A, T2-weighted images demonstrate a heterogeneous right renal mass with a high signal intensity (SI) centrally (red arrows). B, T1-weighted, fat-suppressed precontrast image reveals a central low SI (red arrow) and peripheral isointensity. C, T1-weighted, fat-suppressed postcontrast image demonstrates peripheral enhancement of the renal mass (red arrows) with lack of enhancement centrally.

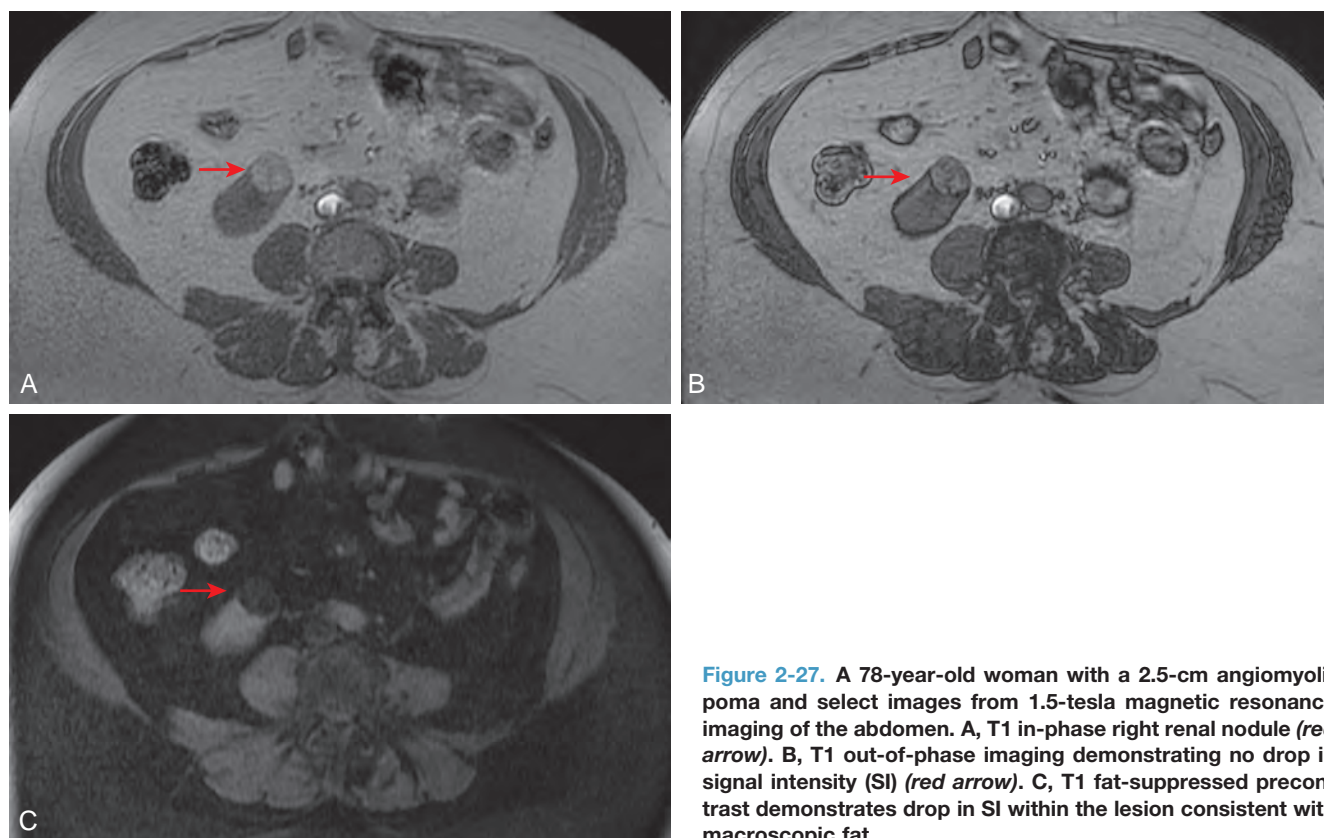

Figure 2-27. A 78-year-old woman with a 2.5-cm angiomyolipoma and select images from 1.5-tesla magnetic resonance imaging of the abdomen. A, T1 in-phase right renal nodule (red arrow). B, T1 out-of-phase imaging demonstrating no drop in signal intensity (SI) (red arrow). C, T1 fat-suppressed precontrast demonstrates drop in SI within the lesion consistent with macroscopic fat.

TABLE 2-4 Magnetic Resonance Imaging Characteristics of Renal Masses

	SIGNAL INTENSITY (SI) % CHANGE			ADC AT B VALUES 0 AND 800 sec/mm ² ($\times 10^{-6}$ mm ² /sec)	T2-WEIGHTED IMAGES SI
	CORTICOMEDULLARY PHASE	NEPHROGENIC PHASE	EXCRETORY PHASE		
Clear cell	230%	250%	227%	1698	High SI heterogeneous
Papillary carcinoma	49%	92%	88%	884	Low SI homogeneous
Chromophobe carcinoma	98%	183%	159%	1135	High T2-weighted SI for central scar
Oncocytoma	208%	265%	237%		High T2-weighted SI for central scar
Angiomyolipoma	353%	285%	222%		Variable
Renal parenchyma				2303	
Transitional cell carcinoma				<450	High signal

ADC, apparent diffusion coefficient.

From Vargas HA, Chaim J, Lefkowitz RA, et al. Renal cortical tumors: use of multiphasic contrast-enhanced MR imaging to differentiate benign and malignant histologic subtypes. *Radiology* 2012;264:779–88; and Wang H, Cheng L, Zhang X, et al. Renal cell carcinoma: diffusion-weighted MR imaging for subtype differentiation at 3.0 T. *Radiology* 2010;257:135–43.

with peak enhancement occurring at 2 to 4 minutes (Ho et al, 2002). Using the specific characteristics of DCE MR sequences, Vargas and colleagues (2012) assessed the enhancement characteristics of cRCC, pRCC, AML, and chromophobe carcinoma in the corticomedullary, nephrogenic, and excretory phases. Clear cell demonstrated greater than 200% SI increase in all three contrast phases, which was significantly higher than chromophobe and papillary carcinoma (Table 2-4). AML was the only renal mass to demonstrate a decrease in SI from the corticomedullary phase to the nephrogenic phase (see Fig. 2-27). Because of a high degree of overlap, it is difficult to assign cutoff points. It was not possible to find characteristics to differentiate oncocytoma from cRCC (Israel and Bosniak, 2003).

Oncocytoma is typically described with a central scar that is observed as a high SI on T2-weighted images. However, this is present only in 54% to 80% of cases (Cornelis et al, 2013). Unfortunately, a central scar has also been reported in 37% of chromophobe carcinomas (Rosenkrantz et al, 2010) (see Fig. 2-26). Both oncocytoma and chromophobe carcinomas are usually peripheral and are hypovascular compared with the renal cortex (Ho et al, 2002). Necrosis has a high SI on T2-weighted images and low SI on T1-weighted images, which is the same for the central scar associated with oncocytoma (Harmon et al, 1996).

DWI is able to detect the restricted movement of water protons within the intracellular and extracellular spaces. Wang and Cheng (2010) reported on using a threshold of 1281×10^{-6} mm²/sec and above for differentiating cRCC from non-clear cell carcinomas with a 95.9% sensitivity and 94.4% specificity (see Table 2-4). Central RCC can be differentiated from transitional cell carcinoma (TCC) of the renal pelvis by setting a threshold of 451×10^{-6} mm²/sec and below on normalized ADC values, resulting in a 83% sensitivity and 71% specificity for detecting TCC (Wehrli et al, 2013).

Historically, MRI has been reported to be superior to earlier CT imaging techniques when attempting to assess if tumor thrombus is present within the renal vein or inferior vena cava. Currently, MRI and CT have the same performance when evaluating for tumor thrombus (Hallscheidt et al, 2005). Gd-contrast agent is used to differentiate tumor thrombus, which exhibits enhancement, compared with a bland thrombus (clot), which exhibits no enhancement.

The size of the lymph nodes observed via MRI and CT is used to detect lymphadenopathy. Several investigators have been evaluating the use of nanoparticles that are composed of superparamagnetic iron oxide in the evaluation of lymphadenopathy (Eisner and

Feldman, 2009). Normal lymph nodes take up the iron oxide particles via phagocytosis, which results in a signal loss on T2-weighted sequences.

Upper Tract and Lower Tract Imaging for Urothelial Carcinoma

Urothelial carcinoma of the upper tract can be assessed by an MR urogram (MRU) in addition to the standard renal mass MRI techniques. MRU can be used in patients for whom other imaging modalities are contraindicated. MRU is accomplished by using heavily weighted T2 sequences in which fluid/urine have a high SI on T1-weighted images with Gd (Chahal et al, 2005). MRU and CTU have the same accuracy in assessing renal obstruction (Silverman et al, 2009). Nephrolithiasis/calcification on MRI has no signal characteristics; therefore it appears as a void on imaging. Urothelial tumors, blood clots, gas, or sloughed renal papilla may exhibit a low signal or signal voids on T2-weighted images secondary to the high signal of urine (Kawashima et al, 2003).

MRI is advantageous over CT imaging of the bladder because of the increased signal contrast between the layers of the bladder. This allows for differentiation between invasive and superficial bladder cancer with an accuracy of 85% (Tekes et al, 2005) (Fig. 2-28).

Prostate

Prostate cancer is one of the few solid organ malignancies that have not had reliable imaging. Over the past 10 years several developments have led to the increased use of MRI for the detection of prostate cancer. The increase in the field strength of magnets from 1 to 3 tesla improved techniques and surface coils have increased the signal contrast (differentiation of normal prostate versus cancer) leading to improved visualization within the gland.

Several authors have reported on varying standards that should be used for prostate imaging. The currency in MRI is signal. Signal detection is optimized by using external surface coils and/or an endorectal coil (ERC) and therefore leads to improved image quality. The National Institutes of Health (NIH) recently completed a study comparing the diagnostic accuracy at 3 tesla with and without ERC in the same patients and compared findings to whole mount histopathology. Results indicated a 36% decrease in sensitivity in detecting prostate cancer when the ERC was not used (Turkbey et al, 2014).

Figure 2-28. A 51-year-old man with a history of gross hematuria underwent a 1.5-tesla magnetic resonance urogram. A, T2 fat-saturated sequence with high T2 signal in bladder (urine). Right bladder wall low signal intensity filling defect (red arrow). B, Fat-suppressed T1 postcontrast arterial phase shows enhancing right bladder wall polypoid mass and is without bladder wall invasion. C, Fat-suppressed T1 delayed contrast imaging shows high signal in bladder consistent with intravenous contrast excretion. Mild persistent signal in right bladder wall mass. D, Heavily weighted T2 urogram selectively demonstrates high signal of fluid within the ureters and bladder. Right wall bladder filling defect (red arrow) is evident. Transurethral resection of bladder tumor confirmed no bladder wall invasion of a high-grade papillary urothelial carcinoma.

Prostate MRI is usually referred to as a multiparametric (MP) MRI. This consists of anatomic and functional imaging techniques. Anatomic imaging should include T1- and T2-weighted images. Functional imaging includes DWI with ADC maps, DCE sequences, and possibly spectroscopy. MR spectroscopy is not always included in the standard MP-MRI. MR spectroscopy takes approximately 15 minutes to perform, is labor intensive, and may not add additional information to affect the clinical interpretation of the study.

Initial T1-weighted sequences are obtained to determine if hemorrhage is present within the prostate; this may limit the diagnostic interpretation of the study. If there is hemorrhage, it can lead to false positives on T2 sequences, DWI/ADC, and DCE images, although some authors report no difference in diagnostic accuracy with or without hemorrhage present (Rosenkrantz et al, 2010). There is debate regarding the time between biopsy and the MP-MRI, which can be performed 3 to 8 weeks after a biopsy to optimize

intraprostatic anatomy (Ikonen et al, 2001; Qayyum et al, 2004; Muller et al, 2014). The wait period is not required for presurgical staging to determine if there is extraprostatic extension (EPE) and/or seminal vesicle invasion (SVI).

The most recent consensus meeting reported that the minimum examination should be a 1.5-tesla MRI with an ERC or a 3 tesla with or without an ERC and a multiparametric approach (Muller et al, 2014). Use of external phased array coils increases signal detection and therefore improves image quality. A 3-tesla MP-MRI with a minimum of 16-channel phased array coil with an ERC detects the highest signal and therefore provides the highest quality images. However, it is unclear if a radiologist needs this level of quality to make a diagnostic impression. It is important that an ERC should never be filled with air or water (Rosen et al, 2007). The result is a decrease in the performance of the T2, DWI, and MR spectroscopy. The most optimal fluids are diamagnetic and proton neutral (Rosen et al, 2007).

T2-Weighted Imaging

T2-weighted sequences of the prostate provide anatomic information and should include triplanar (axial, coronal, and sagittal) sequences. These images provide a detailed anatomic assessment of the gland. The normal peripheral zone appears as an area of high SI. The central gland with benign prostatic hyperplasia (BPH) appears as areas of well-demarcated nodules with heterogeneous SIs. Areas of low SI on T2-weighted sequences can represent prostate cancer or prostatitis, atrophy, scars, hemorrhage after prostate biopsy, and/or BPH nodules (Barentsz et al, 2012). Rarely, BPH nodules can be observed within the peripheral zone and can lead to a false-positive MRI for cancer (Fig. 2-29).

T2-weighted imaging alone results in 58% sensitivity and 93% specificity for detecting prostate cancer within the gland at 3 tesla with an ERC (Turkbey et al, 2011). These limitations reinforce the need to perform a multiparametric assessment that incorporates functional imaging and increases the positive predictive value (PPV) and negative predictive value (NPV) of the examination to greater than 90% (Turkbey et al, 2011). T2-weighted sequences are used to assess EPE and SVI. These areas are represented by low SI. MP-MRI at 3 tesla with an ERC has an approximate 90% accuracy when assessing EPE on a per lesion analysis. At the patient level, comparing the accuracy of staging, including microscopic EPE, overall accuracy decreased to 78.5%. The use of ERC improves the accuracy of detecting EPE and SVI (Heijmink et al, 2007).

Diffusion-Weighted Imaging/Apparent Diffusion Coefficient

DWI assesses the diffusion of water (Brownian motion) within the magnetic field. The MR magnet is able to detect the phase shift changes in the motion of the water protons. The more cellular a

tissue is, the closer the cells are together, resulting in a limited motion of water, which is reflected as a high signal on DWI (Manenti et al, 2006).

As with all MR sequences, there are several details that one should observe. Most important is the b-values associated with DWI. B-values represent a threshold for detecting restriction. As a b-value is increased, less restricted tissues do not exhibit a high signal on DWI. DWI can include multiple b-values, and it is recommended to include at least one b-value greater than 1000 (Rosenkrantz et al, 2010). The ADC is a quantitative assessment of the DWI. This is represented by an area of low signal on the images (dark spot) (Fig. 2-30D). Some authors recommend including a b-2000 sequence on DWI; it has been shown that prostate cancer exhibits a high SI compared with the rest of the gland (Ueno et al, 2013) (Fig. 2-30F).

The ADC value computed from DWI has been shown to directly correlate with Gleason score (Turkbey et al, 2011). Intuitively this makes sense because an increase in cellularity results in an increase in Gleason score. The extracellular/intracellular spaces between the cells are decreased and therefore are reflected as areas of increased restriction.

Dynamic Contrast Enhanced Magnetic Resonance Imaging

DCE-MRI refers to T1-weighted imaging with Gd-based contrast agents. DCE-MRI is not a simple assessment of enhancement versus no enhancement. It assesses vascular permeability and perfusion of the prostate by obtaining multiple image acquisitions over 5 to 10 minutes at a temporal resolution of less than or equal to 5 seconds (Verma et al, 2012). The 5-second temporal resolution requires a decrease in the size of the imaging matrix, therefore resulting in a lower resolution image. DCE-MRI is not meant to obtain clear

Figure 2-29. A 66-year-old man with a prostate-specific antigen of 7.0 and two prior negative biopsies. A 3-tesla multiparametric magnetic resonance imaging (MP-MRI) with an endorectal coil of the prostate was obtained. There were two suspicious areas. A, D, and E, Triplanar images in axial, sagittal, and coronal planes. The peripheral zone (white arrow) and the central gland (yellow arrow) are well visualized. The red arrow represents a well-circumscribed heterogeneous benign prostatic hypertrophy nodule (11 mm × 11 mm × 14 mm) within the peripheral zone with no communication to the central gland. The corresponding apparent diffusion coefficient map (B) demonstrates areas of heterogeneous restriction (761 × 10⁻⁶ mm²/sec). The lesion on the dynamic contrast enhanced MRI (DCE-MRI) (C) exhibits focal type 2 and 3 enhancement curves. The DCE-MRI quantitative analysis is listed (F). The patient underwent a fusion biopsy. The lesion was also appreciated on ultrasonography, and no cancer was detected.

Figure 2-30. A 65-year-old man with a prostate-specific antigen of 38.9 and 16 prior negative biopsies with magnetic resonance (MR) ultrasound fusion biopsy proven Gleason 4 + 4 prostate cancer. **A**, T2-weighted image with an anterior lesion within the central gland, 3.5 cm × 2.7 cm × 3.5 cm (red arrow). **B** and **H**, Dynamic contrast enhanced MRI (DCE-MRI) with color mapping exhibiting a focal type 3 enhancement curve. **C**, Elevated K^{trans} (transfer constant). **D**, Apparent diffusion coefficient map with low signal. **E**, Elevated K^{ep} (rate constant). **F**, Area under the curve. **G**, B-2000 diffusion-weighted sequence with an area of high signal intensity. **I**, Quantitative summary of the large anterior central gland lesion.

anatomic images; it is used to assess the blood flow and vascular permeability throughout the gland over time.

DCE-MRI provides qualitative, semiquantitative, and quantitative information regarding enhancement within the prostate. A qualitative approach consists of visually assessing early enhancement and early washout within the prostate. The use of computer-aided diagnostic systems allows one to obtain specific information with regard to enhancement characteristics. A semiquantitative approach assesses enhancement over time (Tofts et al, 1991). There are three distinct curves associated with prostate imaging (Fig. 2-31). Because of the overlap of all three curve types with benign conditions, it is useful to combine these approaches in a MP-MRI. A quantitative assessment for cancer was first proposed by Tofts and colleagues (1991), observing the pharmacokinetics of the contrast within the gland. K^{trans} (transfer constant) represents the transfer rate (permeability) of contrast between the intravascular space and the extracellular space (or blood flow) to the tissues depending on the hemodynamics at the time of the study. K^{ep} (rate constant) is the rate of efflux of contrast back into the vascular space (Tofts et al, 1999). These quantitative metrics have not been incorporated in the daily work flow of most radiologists; however, they are currently being evaluated for possible decision analysis software (see Fig. 2-30C, D, E, H).

DCE-MRI has a reported 46% to 96% sensitivity and a 74% to 96% specificity for detecting prostate cancer. These large ranges can be the result of the high variability related to patient selection, MRI technique, pathology correlation, and reader experience (Tofts et al, 1991).

Magnetic Resonance Spectroscopy

Proton MR spectroscopic imaging (MRSI) is able to detect the concentration of citrate, choline, and creatine within the prostate. As

cells go through malignant transformation, citrate decreases and creatine and choline levels increase secondary to increased cellular turnover (Choi et al, 2007). An increase of two standard deviations of choline-to-citrate ratio is indicative of cancer (Kurhanewicz et al, 1996). This process is time consuming (15 minutes and has fallen out of favor when used in a nonresearch setting. Turkbey and colleagues (2011) reported only a 7% increase in PPV and NPV using MRSI. Therefore the additional time may not clinically impact cancer detection rates. There is still a significant research potential associated with MRSI. Some authors are using MRSI assessment of cellular metabolism (choline, creatine, and citrate) to evaluate recurrence after radiation therapy (Zhang et al, 2014).

Multiparametric Magnetic Resonance Imaging

The combination of T2, DCE, and DWI has yielded both NPV and PPV greater than 90% (Turkbey et al, 2011; Abd-Alazeez et al, 2014). It is important to understand that high-quality MRI requires tuning of the MR magnets, a dedicated staff to perform the studies, and pathology correlation for the radiologists. There are thousands of settings one can adjust to obtain high-quality images. It is important to start with the basics, which are outlined in European Society of Urogenital Urology (ESUR) 2012 guidelines (Barentsz et al, 2012). If an ERC is used during the study, an antispasmodic agent should be used to decrease the artifact created by rectal spasms. Also, to get the highest quality images, the MR technologist should actively review images during the study and make adjustments or repeat sequences as needed. The goal is to have a prostate MRI scanning time of 30 minutes or less to maintain economical feasibility. Using new magnets with higher field strength, external coils, and an ERC can decrease image acquisition time and may also improve image quality (Heijmink et al, 2007) (Fig. 2-32).

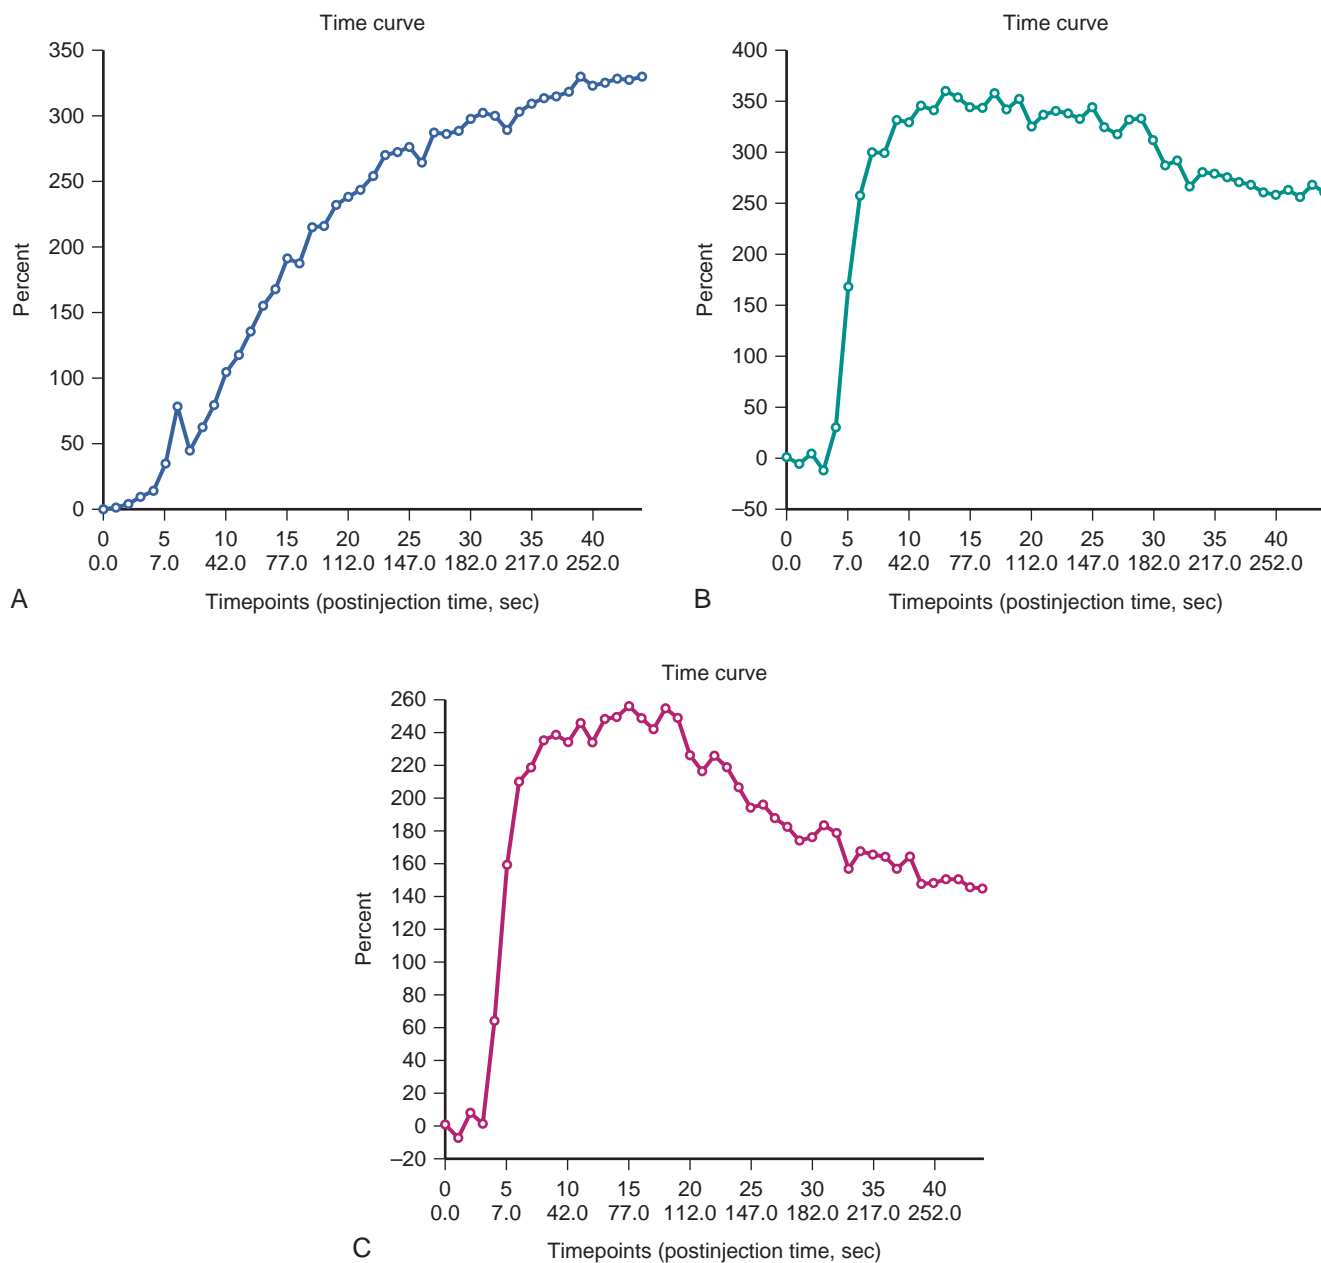

Figure 2-31. A, Type 1 curve is normal enhancement with persistent increase in enhancement over time. B, Type 2 curve is early enhancement with a plateau (no washout). C, Type 3 curve, which is the most indicative of prostate cancer, can overlap with inflammation; this is characterized by early enhancement with an early washout of contrast.

As more physicians begin to use MP-MRI of the prostate, maintaining quality and improving interpretation is extremely important. Each center should have designated readers. Prostate MRI is like no other study in radiology; it benefits from consensus reading and pathology correlation (Muller et al, 2014). Currently, there is no consensus on how a prostate MRI report should be completed. An international working group attempted to standardize reporting for MR targeted biopsies (Moore et al, 2013). The group used predefined prostate zones dividing the prostate into apex, mid, and base (Fig. 2-33A). Unfortunately, these zones do not always correlate well with end-fire images in the United States. However, if slices are used instead of the predefined zones, urologists can use the information regarding sequence, slice number, and primary zones to find the suspicious area within the prostate to aid in targeting during biopsy and possible surgical planning (Fig. 2-33B). In addition to location and 3D size, the radiologist's report should include a score for clinical

suspicion of disease. Multiple scoring systems exist; objective criteria for each sequence can be reported using the Prostate Imaging Reporting and Data System (PI-RADS) and the NIH scoring systems, as well as a subjective assessment using a five-point Likert scale for each lesion and the overall clinical suspicion for the patient (Barentsz et al, 2012; Moore et al, 2013; Turkbey et al, 2014) (Box 2-2).

In summary, MP-MRI of the prostate is a potential new tool that is able to detect, quantify, stage, and influence treatment planning for patients with prostate cancer. MP-MRI has also been shown to correctly select patients with low-grade/low-volume disease for active surveillance with an accuracy of 92% (Turkbey et al, 2014). MP-MRI of the prostate also provides information on possible bone involvement or lymphadenopathy at the time of diagnosis. The accuracy of MRI detecting lymphadenopathy has a sensitivity up to 86% and specificity of 78% to 90% (Talab et al, 2012).

Figure 2-32. A 61-year-old Caucasian man with an increasing prostate-specific antigen (4.65 ng/mL) after a prior negative biopsy 1 year ago. Three-tesla multiparametric magnetic resonance imaging (MP-MRI) of the prostate with an endorectal coil was obtained. **A**, T2-weighted image with a homogeneous low signal intensity (SI) lesion within the right posterior peripheral zone (red arrow). **B**, Apparent diffusion coefficient (ADC) map with a corresponding low SI to the T2 sequence. **C**, Dynamic contrast enhanced MRI (DCE-MRI) with color mapping exhibiting a focal type 3 enhancement curve. **D**, Sagittal T2 sequence with a low-signal lesion within the peripheral zone. **E**, B-2000 diffusion-weighted imaging with high signal corresponding to T2, ADC, DCE abnormalities. **F**, Type 3 enhancement curve. The pathology was Gleason 3+4 prostate cancer, zone 3L, volume 0.3 mL (9 mm × 8 mm × 9 mm).

Magnetic Resonance Ultrasound Fusion-Guided Prostate Biopsy

MR ultrasound fusion-guided prostate biopsy is the next step in the integration of high-quality intraprostatic imaging for screening and diagnosing prostate cancer. There are multiple fusion biopsy systems on the market. The performance of these systems differs slightly from one vendor to the other. However, the most important factor is the quality of the MP-MRI and abilities of the imaging team. These two factors have been shown to result in increased cancer detection rates in patients undergoing targeted biopsies (Pinto et al, 2011; Sonn et al, 2013).

Currently, a targeted biopsy or MP-MRI alone is not an alternative to the standard of care in screening men for prostate cancer. MP-MRI offers a distinct advantage when selecting men to undergo a biopsy with an elevated PSA. PSA is not prostate cancer specific and can be elevated for numerous reasons, including inflammation/infection, BPH, and physical manipulation. The MRI is able to assess BPH and inflammation before biopsy, and this may allow men who have persistently elevated PSA and an initial negative 12-core biopsy to avoid undergoing a second biopsy. Additionally, MP-MRI of the prostate can detect intermediate- and high-risk disease, but it has difficulty detecting low-grade/low-volume cancers, which may decrease overdiagnosis and overtreatment of clinically insignificant disease. Moore and colleagues (2013) reported that 38% of men with an elevated PSA did not have any visible lesions on MP-MRI. In this study, a 12-core biopsy detected only clinically significant cancer for 2.3% of the patients (Gleason score ≥ 7 or a core length of >5 mm).

The MR ultrasound fusion-guided biopsy has the advantage of using the MRI to target specific areas (i.e., anterior or central gland lesions) within the prostate that may be missed on a standard systematic 12-core biopsy. In addition, the 12-core biopsy may miss many lesions within the peripheral zone.

The cancer detection rates for targeted biopsies are superior to using the information from the MRI and then attempting to cognitively find the same area on ultrasonography to perform the biopsy (Wysock et al, 2014). The cancer detection rates for these types of targeted biopsies in patients with moderate to high suspicion on MRI are approximately 50% to 72% (Pinto et al, 2011; Sonn et al, 2013; Rastinehad et al, 2014).

All these new technologies do come at a cost. However, if one is able to select specific areas of the prostate to be targeted, instead of performing a 12-core biopsy, the savings from the decrease in number of pathology specimens collected could offset the cost of the MRI (Rastinehad et al, 2014). There is mounting evidence that a negative MP-MRI may effectively rule out a patient having clinically significant disease. The group from the University College London reported that a MP-MRI has an 89% to 100% NPV for ruling out clinically significant prostate cancer in patients with a negative MP-MR (Abd-Alazeez et al, 2014). This may result in patients foregoing a prostate biopsy and avoiding associated side effects.

ACKNOWLEDGMENTS

Thank you to the Drs. Ben-Levi, Villani, and Friedman for their help acquiring and reviewing images.

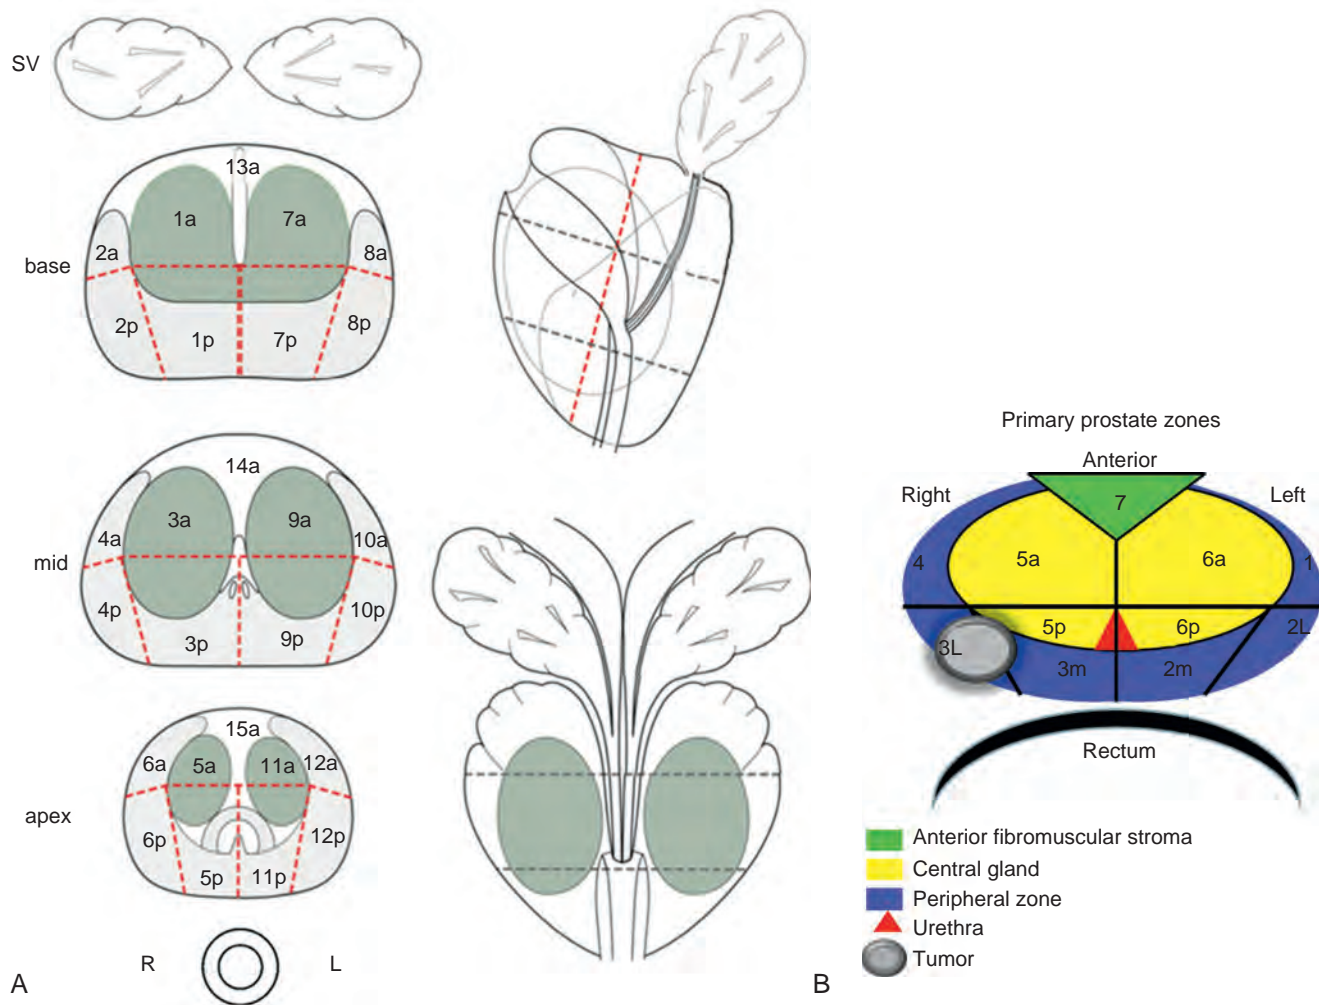

Figure 2-33. A, Standards of reporting for MRI-targeted biopsy studies (START) reporting zones. SV, seminal vesicle. B, Primary prostate zones for reporting. The lesion is marked in the T2-weighted sequence because this is typically the sequence used for fusion-guided biopsies. This would be a Zone 3L (lateral) lesion on slice 17 (see Fig. 2-32). The slice levels for base and apex of the prostate are also reported. This allows one to convert the information to the START criteria zones for publication; however, this approach allows the urologist to locate the lesion on the multiparametric magnetic resonance image with ease (sequence, slice number, and zone number).

BOX 2-2 Five-Point Likert Scale for Prostate Imaging

1. Clinically significant disease is highly unlikely to be present.
2. Clinically significant disease is unlikely to be present.
3. Clinically significant disease is equivocal.
4. Clinically significant disease is likely to be present.
5. Clinically significant disease is highly likely to be present.

KEY POINTS: MRI

- When a renal mass is seen on MRI, the most important characteristic indicating the presence of a malignancy is enhancement of the mass.
- NSF is seen in patients with severe renal insufficiency who are exposed to Gd contrast media.
- Pheochromocytoma, metastatic lesion to the adrenal gland, and primary ACC are all bright on T2-weighted images.

Urinary Tract Imaging: Basic Principles of Urologic Ultrasonography

Bruce R. Gilbert, MD, PhD, and Pat F. Fulgham, MD

Brief History of Ultrasonography in Urology

Physical Principles

Modes of Ultrasonography

Contrast Agents in Ultrasonography

Documentation and Image Storage

Patient Safety

Clinical Urologic Ultrasonography

Practice Accreditation

Ultrasonography has often been referred to as the “urologist’s stethoscope” because much of the genitourinary system is not easily evaluated by physical examination and requires imaging for diagnosis. Therein lies one of the unique aspects of ultrasound studies performed and interpreted by urologists. The mandate to examine the patient coupled with the urologist’s experience in both surgical and medical treatment engenders an unparalleled ability to meld the healer’s art with advanced imaging technology. In addition, ultrasonography is a versatile and relatively inexpensive imaging modality that has the unique feature of being the only imaging modality to provide real-time evaluation of urologic organs and structures without the need for ionizing radiation. To use this technology best on behalf of their patients, urologists must have a mature understanding of the underlying physical principles of ultrasonography. They must also understand how the manipulation of ultrasound equipment can affect the quality of ultrasound images. The technical skills required to perform and interpret urologic ultrasonography represent a combination of practical scanning ability and knowledge of the underlying disease process in organs being imaged. To communicate the findings appropriately, urologists should understand the nomenclature of ultrasonography and have a specific plan for documentation of each type of study. Understanding how ultrasonography interacts with human tissues allows urologists to use this modality effectively, appropriately, and safely. The aim of this chapter is to encourage urologists to embrace the art and science of ultrasonography in their mission to provide excellence in patient care.

BRIEF HISTORY OF ULTRASONOGRAPHY IN UROLOGY

In 1963, Japanese urologists Takahashi and Ouchi became the first to attempt ultrasonic examination of the prostate. However, the image quality that resulted was not interpretable and carried little medical utility (Takahashi and Ouchi, 1963). Wild and Reid (1952) also attempted transrectal ultrasonography (TRUS) but were met with the same result. Progress was not made until Watanabe and colleagues (1974) demonstrated radial scanning that could adequately identify prostate and bladder pathology. Using a purpose-built device modeled after a museum sculpture entitled “Magician’s Chair,” Watanabe seated his patients on a chair with a hole cut in the center such that the transducer tube could be passed through the hole and into the rectum of the seated patient (Watanabe et al, 1974). Images from Watanabe’s seated probe are shown in Figure 3-1. As is evident in Figures 3-1B (demonstrating an area of circumscribed symmetric echogenicity, representing benign prostatic

hyperplasia), and 3-1C (demonstrating an asymmetric area of hyperechogenicity, representing prostate cancer), resolution was poor, and images displayed extreme contrast. Subsequent development of biplanar, high-frequency probes created increased resolution and allowed for TRUS to become the standard for diagnosis of prostatic disease.

In 1971 Goldberg and Pollack, frustrated with the inability of intravenous pyelography to differentiate benign from malignant lesions, employed A-mode ultrasonography to evaluate the kidney. In their report on “nephrosoundography,” they demonstrated in a series of 150 patients the capability of ultrasonography to discern solid, cystic, and complex masses with an accuracy of 96%. Diagrammatic representations of the three ultrasound patterns they found are depicted in Figure 3-2 (Goldberg and Pollack, 2002). In cystic lesions, the first spike represents the striking of the front wall of the cyst and the second spike represents the striking of the back wall. More complex lesions have return of more spikes.

In 1974 Holm and Northeved introduced a transurethral ultrasonic device that would be interchangeable with conventional optics during cystoscopy for the purpose of imaging the prostate and bladder. Their other goals for this device included the ability to determine depth of bladder tumor penetration, to determine prostatic volume, to evaluate prostatic tumor progression, and to assist with transurethral resection of the prostate (Holm and Northeved, 1974).

Perri and colleagues were the first to use Doppler as a sonic “stethoscope” in their work-up of patients with an acute scrotum in 1976. Although they were able to identify patients with epididymitis and torsion of the appendix testis as having increased flow and patients with spermatic cord torsion as having no blood flow, they also reported that false-negative images in cases of torsion could result from increased flow secondary to reactive hyperemia (Perri et al, 1976).

Watanabe and colleagues (1976), pioneers in the use of ultrasonography in urology, demonstrated that Doppler could be used to identify the renal arteries in a noninvasive way in 1976, and Greene and colleagues (1981) documented 5 years later that Doppler could adequately differentiate stenotic from normal renal arteries. In 1982 Arima and associates used Doppler to differentiate acute from chronic rejection in patients with renal transplants, noting that acute rejection is characterized by the disappearance of diastolic phase, with reappearance being indicative of recovery from rejection. These authors concluded that Doppler could guide the management of rejection as an index for steroid therapy (Arima et al, 1982).

Figure 3-1. A, Watanabe's chair. B, Display of patient with benign prostatic hyperplasia. C, Display of prostate cancer. (From Watanabe H, Igari D, Tanahasi Y, et al. Development and application of new equipment for transrectal ultrasonography. *J Clin Ultrasound* 1974;2:91–8.)

Figure 3-2. Goldberg and Pollack were the first to differentiate between solid, complex, and cystic masses by ultrasonography. In cystic lesions, the first spike represents the striking of the front wall of the cyst, and the second spike represents the striking of the back wall. More complex lesions have return of more spikes. (From Goldberg B, Pollack H. Differentiation of renal masses using A-mode ultrasound. *J Urol* 2002;167:1022–6.)

In the early 1990s numerous authors investigated the therapeutic uses of high-intensity focused ultrasonography (HIFU). Following prior reports of histologic changes after HIFU (Burgess et al, 1987), Madersbacher and colleagues (1993) were the first to report the safety and efficacy of HIFU in patients with symptomatic benign prostatic hyperplasia. The utility of HIFU in the treatment of testicular cancer (Madersbacher et al, 1998), early prostate cancer (Chapelon et al, 1999), recurrent prostate cancer (Berge et al, 2010), and renal cell cancer transcutaneously (Köhrmann et al, 2002) and laparoscopically (Margreiter and Marberger, 2010) was soon explored as well.

The field of urology continues to demand and discover novel uses for ultrasound technology. Chen and coworkers (2010) used TRUS guidance to inject botulinum toxin into the external urethral sphincters of a series of patients with detrusor external sphincter dyssynergia. Ozawa and colleagues (2010) used perineal ultrasound video-urodynamics to diagnose bladder outlet obstruction accurately in a noninvasive manner. The possibilities for application of ultrasonography in diagnosing or treating urologic conditions are endless.

Urologic ultrasonography continues to evolve with the use of contrast agents and new modalities such as sonoelastography that include groundbreaking discoveries and new applications of basic

physical principles. This homage to the innovators of the past serves both to recognize prior achievements and to acknowledge that future work in the development of new applications for ultrasonography will always be needed.

PHYSICAL PRINCIPLES

All ultrasound imaging is the result of the interaction of sound waves with tissues and structures within the human body. Ultrasound waves are produced by applying short bursts of alternating electrical current to a series of crystals housed in the transducer. Alternating expansion and contraction of the crystals via the piezoelectric effect creates a mechanical wave that is transmitted through a coupling medium to the skin and then into the body. The waves that are produced are longitudinal waves. In a longitudinal wave, the particle motion is in the same direction as the propagation of the wave (Fig. 3-3). This motion produces areas of rarefaction and compression of tissue in the direction of travel of the ultrasound wave (Fig. 3-4). A portion of the wave is reflected toward the transducer. The transducer serves as a receiver and “listens” for the returning sound wave reconverts the mechanical wave to electrical energy. The transducer must be in direct,

Figure 3-3. The alternating expansion and contraction of the crystal produces longitudinal mechanical waves. In this simplified schematic drawing, the individual molecules (depicted as circles) are displaced in the direction of the propagated wave.

Figure 3-4. Areas of compression alternating with areas of rarefaction are depicted as a sine wave. The wavelength (λ) is the length from peak compression to peak compression in this drawing. This graphic depiction is critical to understanding the behavior of sound waves in the human body and how ultrasound images are generated. (From Merritt CRB. *Physics of ultrasound*. In: Rumack CM, Wilson SR, Charboneau JW, Johnson J, editors. *Diagnostic ultrasound*. 3rd ed. St. Louis: Mosby; 2005. p. 3–34.)

secure contact with the subject to transmit and receive the reflected sound waves.

The appearance of the image produced by ultrasonography is the result of the interaction of mechanical ultrasound waves with biologic tissues and materials. Because ultrasound waves are transmitted and received at frequent intervals, the images can be rapidly reconstructed and refreshed, providing a real-time image. The frequencies of the sound waves used for urologic ultrasound imaging are in the range of 3.5 to 12 MHz.

Mechanical waves are represented graphically as a sine wave alternating between a positive and negative direction from the baseline. In the case of ultrasonography, the amplitude of the sine wave describes differences in pressure. Ultrasound waves are described using the standard nomenclature for sine waves. A wavelength (λ) is described as the distance between one peak of the wave and the

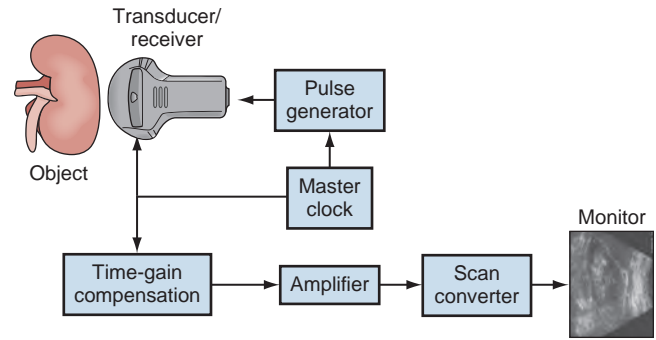

Figure 3-5. In this simplified schematic diagram of ultrasound imaging, the ultrasound wave is produced by means of a pulse generator controlled by a master clock. The reflected waves received by the transducer are analyzed for amplitude and transit time within the body. The scan converter produces the familiar picture seen on the monitor. The actual image is a series of vertical lines that are continuously refreshed to produce the familiar real-time, gray-scale image.

next peak. The complete path traveled by the wave from one peak to the next is called a *cycle*. One cycle per second is known as 1 hertz (Hz). The “period” is the time it takes for one complete cycle of the wave.

The “amplitude” of a wave is the maximal excursion in the positive or negative direction from the baseline. Amplitude corresponds to the mechanical energy associated with the sound wave and is a key property in assigning pixel brightness to a gray-scale ultrasound image. The greater the amplitude, the brighter is the corresponding pixel.

Ultrasound Image Generation

The image produced by an ultrasound machine begins with the transducer. In ultrasound imaging, the transducer has a dual function as a sender and a receiver. Sound waves are created in short pulses and transmitted into the body and are then at least partially reflected. Reflected mechanical sound waves are received by the transducer and converted back into electrical energy. The transducer acts as a receiver more than 99% of the time. The electrical energy is converted by the ultrasound machine to an image displayed on a monitor (Fig. 3-5).

Resolution

The resolution of an ultrasound image refers to the ability to discriminate two objects in close proximity to one another. **Axial resolution** refers to the ability to identify as separate two objects in the direction of the traveling sound wave. Axial resolution is directly dependent on the frequency of sound waves. The higher the frequency of the sound wave, the better the axial resolution. **Lateral resolution** refers to the ability to identify separately objects that are equidistant from the transducer. Lateral resolution is a function of the focused width of the ultrasound beam and is a characteristic of the transducer. The location of the narrowest beam width can be adjusted by the user. The more focused the beam, the better the lateral resolution at that location. Image quality can be enhanced by locating the narrowest beam width (focus or focal zone) at the depth of the object or tissue of interest (Fig. 3-6).

The velocity with which a sound wave travels through tissue is a product of its frequency and wavelength (Fig. 3-7). The **average velocity of sound in human tissues is 1540 m/sec**. Because the average velocity of sound in tissue is a constant, changes in frequency result in changes in wavelength.

The optimal ultrasound image requires tradeoffs between resolution and depth of penetration. High-frequency transducers of 6 to 10 MHz may be used to image structures near the surface of the

Figure 3-6. The shape of the ultrasound beam is simulated in this drawing (purple). The focal zone (A) is located to produce the best lateral resolution of the medial renal cortex. The location of the focal zone is designated by the caret (B). The location of the focal zone can be adjusted by the operator.

$$v = f \times \lambda$$

velocity = frequency × wavelength

Figure 3-7. The relationship between velocity, frequency, and wavelength of sound waves in tissue. Wavelength and frequency vary in an inverse relationship.

body (e.g., testis, pediatric kidney) with excellent resolution. However, deeper structures (e.g., right kidney, bladder) require lower frequencies of 3.5 to 5 MHz to penetrate. Such images have poorer axial resolution.

Mechanisms of Attenuation

As sound waves transit tissues, energy is lost or attenuated. Mechanisms of attenuation include **reflection, scattering, interference, and absorption**. Reflection is the key physical phenomenon that allows for information to return to the transducer as mechanical energy. Reflection occurs when ultrasound waves strike an object, a surface, or a boundary (called an **interface**) between unlike tissues. The shape and size of the object and the angle at which the advancing wave strikes the object are critical determinants of the amount of energy reflected. The amount of energy reflected from an interface is also influenced by the **impedance** of the two tissues at the interface. Impedance is a property that is influenced by tissue stiffness and density. The difference in impedance allows an appreciation of interfaces between different types of tissue (Table 3-1).

The impedance difference between perinephric fat and the kidney allows a sharp visual distinction at the interface. If the impedance difference between tissues is small (e.g., between liver and kidney), the interface between the tissues is more difficult to see (Fig. 3-8A). If impedance differences are large, there is

TABLE 3-1 Density and Impedance of Tissues Encountered During Urologic Ultrasonography

	DENSITY	IMPEDANCE
Air and other gases	1.2	0.0004
Fat tissue	952	1.38
Water and other clear liquids	1000	1.48
Kidney (average of soft tissue)	1060	1.63
Liver	1060	1.64
Muscle	1080	1.70
Bone and other calcified objects	1912	7.8

Figure 3-8. A, In this sagittal view of the right kidney, the paucity of perinephric fat and the small impedance difference make it difficult to distinguish the interface between the kidney and the liver (arrows). B, The large impedance difference at the interface between urine and a bladder stone (arrow) results in significant reflection and attenuation of the sound wave. An acoustic shadow is seen distal to the stone (arrowhead).

significant reflection of the sound wave producing an acoustical shadow distal to the interface (Fig. 3-8B).

Scattering occurs when sound waves strike a small or irregular object. The resulting spherical wave overlaps waves of surrounding scattering objects (Fig. 3-9).

When interacting sound waves are in phase or out of phase, their amplitude is enhanced or diminished. This **pattern of interference** is partially responsible for the echo architecture or texture of organs. One pattern of interference, commonly called “**speckling**” (Fig. 3-10), is seen in organs with fine, internal histology (i.e., reflectors such as the testis).

Absorption occurs when the mechanical energy of the ultrasound waves is converted to heat. Absorption is directly proportional to frequency. The higher the frequency of the incident wave,

Figure 3-9. Scattering is a phenomenon that occurs when sound waves strike small objects. The resulting pattern of energy dispersal often results in interference.

Figure 3-10. Fine internal echogenicity called “speckle” is caused by scattering of sound waves, resulting in a pattern of interference. Note the resulting finely granular, homogeneous echogenicity (arrows) of the testicular parenchyma.

the greater the absorption of energy, and more tissue heating results. It follows that higher frequency waves are more rapidly attenuated and have a limited depth of penetration (Fig. 3-11).

Artifacts

The interaction of ultrasound waves with tissues may produce images that do not reflect the true underlying anatomy. These misrepresentations are called “**artifacts**.” Artifacts may be misleading but, if recognized, may also assist diagnosis. **Acoustical shadowing** occurs when there is significant attenuation or reflection of sound waves at a tissue interface. Echo information posterior to the interface may be obscured or lost. An anechoic or hypoechoic “shadow” is produced. Under these conditions, three-dimensional (3D) objects such as stones may appear as crescentic objects, making it difficult to obtain accurate measurements (Fig. 3-12). Important pathology posterior to such an interface may be missed. This problem may often be overcome or mitigated by changing the angle of insonation, changing the frequency of the transducer, or changing the focal zone of the transducer.

Figure 3-11. Relationship between frequency and tissue penetration. High-frequency sound waves are rapidly attenuated and are unable to penetrate deeply. Conversely, low-frequency waves are less attenuated and able to penetrate deeply to internal structures.

Figure 3-12. In this transverse view of the urinary bladder (B), there are two large bladder diverticula (D). Two stones (arrows) strongly reflect and attenuate the incident sound wave, producing an acoustical shadow. The stones appear crescentic even though they are ovoid in shape.

Increased through-transmission is observed when sound waves are less attenuated while passing through a given structure or tissue than by the surrounding tissues. For example, when imaging a simple cyst of the kidney, sound waves passing through the cyst are less attenuated than sound waves passing through the surrounding renal cortex and renal sinus. When the waves transiting the cyst strike the back wall of the cyst and posterior renal tissue, the waves are more energetic on arrival to these tissues. The reflected sound waves are also more energetic and less attenuated as they return to the transducer. The result is that tissue posterior to the cyst appears hyperechoic compared with the surrounding renal tissue, even though the tissues are histologically identical (Fig. 3-13). The effect of this artifact can be mitigated by changing the angle of insonation or adjusting the time-gain compensation settings.

An **edging artifact** occurs when sound waves strike a curved surface or interface at an incident angle, resulting in refraction of the wave along the plane of the interface (Fig. 3-14). An incident wave at this angle (the critical angle) is not directly reflected to the

transducer, resulting in a hypoechoic “shadow.” This artifact is commonly seen in testicular ultrasonography and TRUS (Fig. 3-15). It can be overcome by changing the angle of insonation.

A **reverberation artifact** results when there are large differences in impedance between two adjacent tissues or surfaces with a strong reflection of the incident wave. The ultrasound wave bounces back and forth (reverberates) between the reflective interfaces. With the second transit of the sound wave, the ultrasound equipment interprets a second object that is twice as far away as the first. There is ongoing attenuation of the sound wave with each successive reverberation, resulting in a slightly less intense image displayed on the screen. Echoes are produced, spaced at equal intervals from the transducer but progressively less intense (Fig. 3-16).

The reverberation artifact can also be seen in cases where the incident sound wave strikes a series of smaller reflective objects (e.g., the gas-fluid mixture in the small bowel), which results in multiple reflected sound waves of various angles and intensity (Fig. 3-17). The resultant echo pattern is a collection of hyperechoic artifactual reflections distal to the structure with progressive attenuation of the sound wave.

Figure 3-13. Increased through-transmission (also called “distal enhancement”) is demonstrated in this longitudinal view of the left kidney. The tissue distal to the cyst appears hyperechoic (arrows) compared with adjacent tissue.

MODES OF ULTRASONOGRAPHY

Gray-Scale Ultrasonography

Gray-scale B-mode ultrasonography is the most commonly employed mode of ultrasonography. This pulsed-wave technique produces real-time two-dimensional images consisting of shades of gray. The generation of this image involves assigning a pixel brightness to the amplitude of the returning sound waves received by the transducer. The position of the pixel is determined by the duration of the round trip of the sound wave. Individual lines of data are displayed sequentially on the monitor to produce a continuous or real-time image. Evaluation of gray-scale imaging requires the ability to recognize normal patterns of echogenicity from anatomic

Figure 3-14. When sound waves strike a surface or interface at a “critical angle,” the wave is refracted without significant reflection.

Figure 3-15. A, The curved surface of the tunica albuginea of the upper pole of the testis creates a critical angle edging artifact (arrows). B, The rounded surfaces of the lateral lobes of the prostate as they meet in the prostatic urethra create an edging artifact (arrows) in this transverse image of the prostate.

structures. Variations from these expected patterns of echogenicity indicate disorders of anatomy or physiology.

Doppler Ultrasonography

Doppler ultrasonography depends on the physical principle of frequency shift when sound waves strike a moving object. The basic principle of Doppler ultrasonography is that sound waves of a certain frequency are shifted or changed on the basis of the direction and velocity of the moving object as well as the angle of insonation. This phenomenon allows for the characterization of motion, most commonly the motion of blood through vessels, but it may also be useful for detecting the flow of urine.

Color Doppler ultrasonography allows for evaluation of the velocity and direction of motion. A color map may be applied to direction with the most common assignment of the color blue to

motion away from the transducer and red to motion toward the transducer. The velocity of motion is designated by the intensity of the color: The brighter the color, the greater the velocity. Color Doppler may be used to evaluate the presence or absence of blood flow in the kidney, testes, penis, and prostate. It also may be useful in the detection of ureteral “jets” of urine emerging from the ureteral orifices.

Color flow with spectral display allows the interrogation of particular areas within an ultrasound field for flow and displays the flow as a continuous waveform. This mode is commonly used to evaluate the pattern and velocity of blood flow in the intrarenal or penile vasculature. The waveform provides information about peripheral vascular resistance in the tissues. The most commonly used index of these velocities is the resistive index. The **resistive index** is peak systolic velocity (PSV) minus the end-diastolic velocity over the PSV. This index is helpful in characterizing many clinical conditions including renal artery stenosis, ureteral obstruction, and penile arterial insufficiency.

Power Doppler ultrasonography assigns the amplitude of frequency change to a color map. This mode does not permit evaluation of velocity or direction of flow but is less affected by backscatter waves and is a more sensitive mode for detecting blood flow. Power Doppler is less angle dependent than color Doppler and is three to five times as sensitive as color Doppler ultrasonography for detecting flow. It may be useful for evaluating testicular torsion.

Figure 3-16. Reverberation artifact. A virtual representation of the strongly reflective interface is projected with decreasing amplitude as the incident sound wave makes multiple round trips.

Harmonic Scanning

Harmonic scanning uses aberrations related to the nonlinear propagation of sound waves within tissue. These asymmetrically propagated waves generate fewer harmonics, but those that are generated have greater amplitudes. Because these harmonics are not subject to scattering at the frequency associated with the incident wave, there is less noise associated with the signal. By concentrating on the harmonic frequencies produced within the body and reflected to the transducer, it is possible to produce an image with less artifact and greater resolution (Fig. 3-18).

Spatial Compounding

Spatial compounding is a scanning mode whereby the direction of insonation is electronically altered, and a composite image is

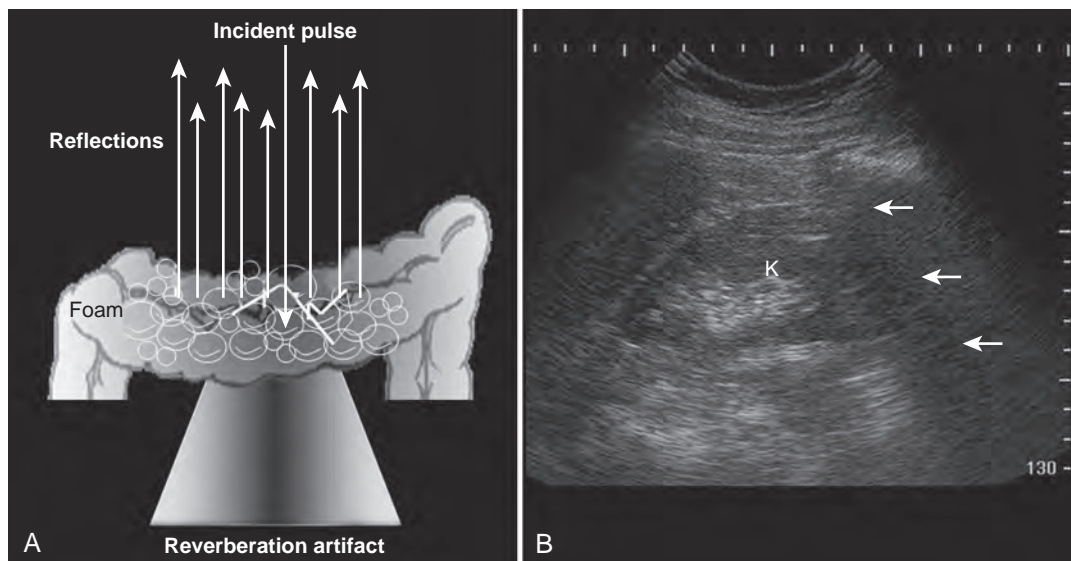

Figure 3-17. When an ultrasound wave strikes a structure such as bowel, which contains gas bubbles (A), the resultant reverberation artifact has a characteristic appearance sometimes called a “comet tail.” B, A comet tail artifact produced by bowel gas (arrows) obscures the lower pole of the kidney (K).

Figure 3-18. A, Standard gray-scale image of a cyst containing a mural nodule (*arrowhead*). Note the artifactual echogenicity within the cyst (*arrow*). B, The same structure on harmonic scanning is seen more clearly. There is less artifact within and distal to the cyst. (From Merritt CRB. *Physics of ultrasound*. In: Rumack CM, Wilson SR, Charboneau JW, Johnson J, editors. *Diagnostic ultrasound*. 3rd ed. St. Louis: Mosby; 2005. p. 3–34.)

generated. This technique reduces the amount of artifact and noise, producing a scan of better clarity.

Sonoelastography

The ability to access pathology by palpation has long been a key part of a physician's physical examination. Hard lesions are often a sign of pathology. Sonoelastography (tissue elasticity imaging) is an evolving ultrasound modality that adds the ability to evaluate the elasticity (compressibility and displacement) of biologic tissues. Essentially, it gives a representation, using color, of the softness or hardness of the tissue of interest. To use ultrasonography to "palpate" an organ requires a compressing mechanical wave to be produced in the tissue of interest. Presently, there are two ways to produce this mechanical wave: real-time elastography (RTE) and shear wave elastography (SWE).

In RTE, as in standard diagnostic ultrasonography, an external, nonquantifiable mechanically produced compression wave travels in tissue (1540 m/sec). These waves successively compress tissue layers producing backscatter reflected waves that are received and processed by the ultrasound equipment producing an image. Because the stress producing the mechanical compression wave cannot be directly measured, only a relative elasticity can be determined.

With RTE (*Fig. 3-19*), deformation is induced by manually pressing on the anatomy with the transducer and is measured using ultrasonography. RTE is a qualitative technique and highly user-dependent. Because of the requirement of manual displacement, RTE is unable to measure absolute tissue stiffness as currently employed. Its major benefits are that it has a high spatial resolution, it is a real-time measurement, and it does not require any modifications to conventional ultrasound hardware. Spatial resolution is the ability to distinguish two separate objects that are close together and encompasses both axial resolution and lateral resolution as defined previously.

Figure 3-19. Real-time elastography. A 4-mm hypoechoic nodule (*arrow, left panel*) was found with Doppler ultrasonography with vascular flow internally. Real-time sonoelastography suggested a hard nodule (with this equipment blue is hard, not soft). Close follow-up with ultrasound examinations every 3 months found no increase in size of the nodule, and it was considered "probably" benign. (From Goddi A, Sacchi A, Magistretti G, Almolla J. Real-time tissue elastography for testicular lesion assessment. *Eur Radiol* 2012;22:721–30.)

In SWE, the shear wave produced can be precisely measured and travels more slowly (1 to 10 m/sec). The shear wave is propagated by a tangential "sliding" force between tissue layers. The elasticity (E), density of the tissue (ρ , kg/m²), and shear wave propagation speed (c) are directly related through the equation $E = 3\rho c^2$. By measuring the shear wave propagation speed, the elasticity of the tissue can be directly determined.

With SWE (*Fig. 3-20*), low-frequency (approximately 100 Hz) pulses are rapidly transmitted into the tissue to induce a vibration in the tissue. Depending on the manufacturer's implementation, the

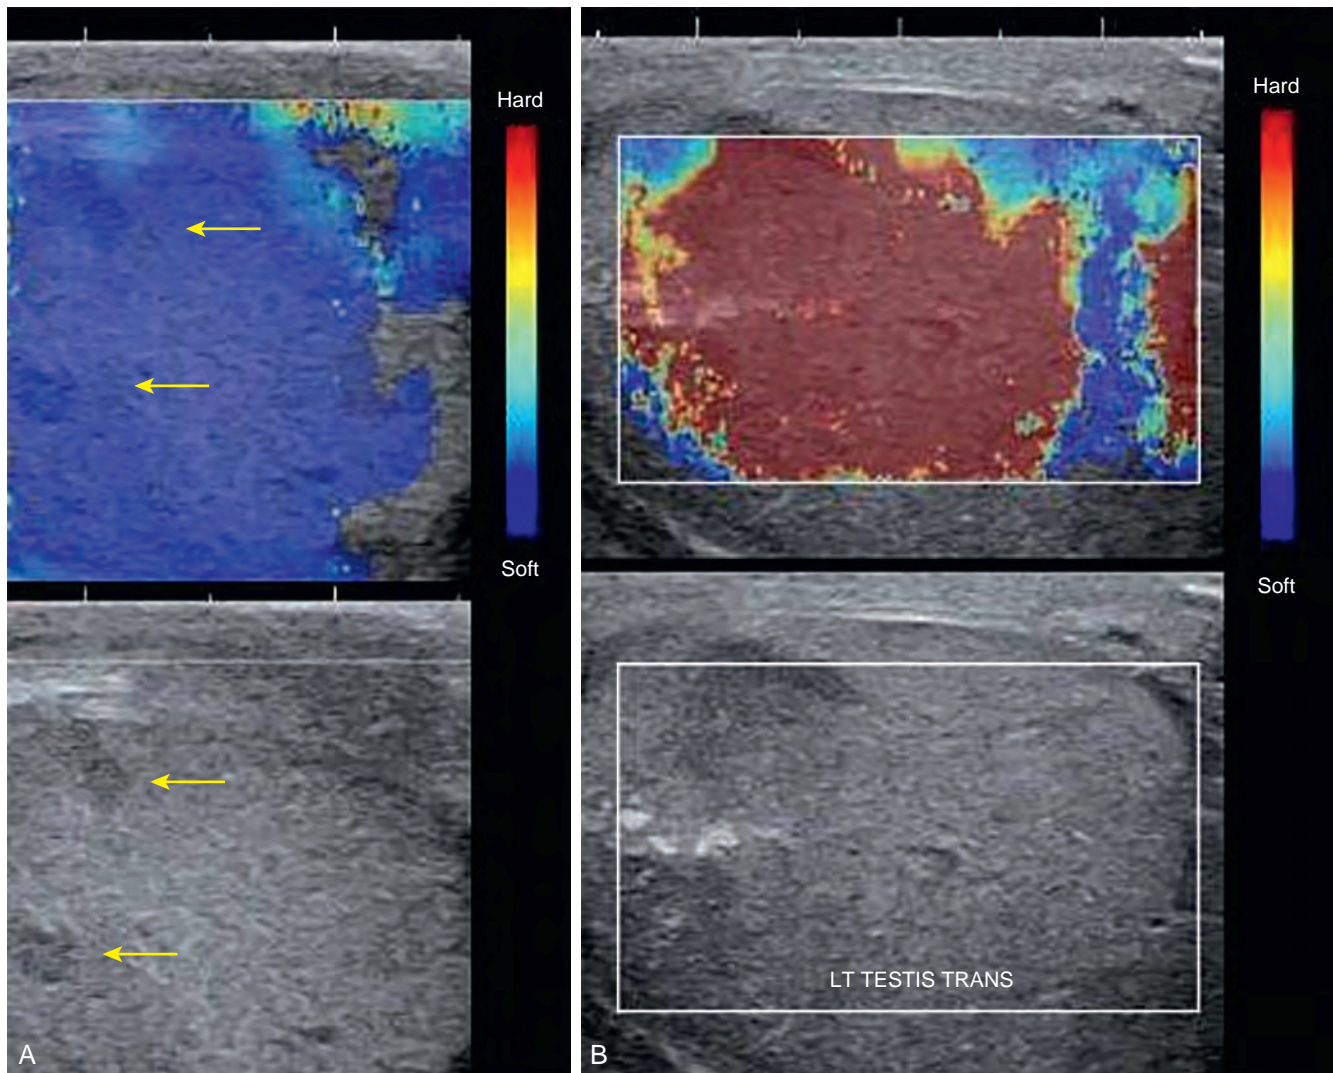

Figure 3-20. Shear wave elastography (SWE). A, Two small hypoechoic vascular lesions (arrows, lower panel) found with B-mode ultrasonography are shown in the upper panel to be soft (blue) lesions with SWE ultrasonography. Biopsy confirmed a Sertoli cell nodule. B, A larger lesion with heterogeneous echogenicity on B-mode ultrasonography (lower panel) demonstrates diffuse “hardness” on SWE (upper panel). Pathology demonstrated a nonseminomatous germ cell tumor.

vibrations can be induced in a single area or in a vertical plane by rapidly altering focal depth. Subsequently, the observation of the propagation velocity of the resultant transient shear waves determines the viscoelastic properties of the tissues. Two typical limitations of generated shear waves are as follows: (1) They are very weak resulting in only a few millimeters of propagation, and (2) detection of shear wave propagation requires very rapid acquisition speeds (pulse repetition frequency is >5000 Hz), which may limit the area of detection. However, some new-generation ultrasound systems have overcome these obstacles and allow large areas of interest to be displayed at near real-time imaging frame rates.

Several approaches for elastography have been introduced. All of them have three common steps, as follows:

1. The sonographer manually compresses (RTE) or the machine automatically generates (SWE) a low-frequency vibration in tissue to induce stress.
2. The tissue is imaged with the goal of analyzing the resulting strain.
3. Parameters are defined related to tissue stiffness.

The principle of elastography is based on the concept that a given force applied to softer tissue results in a larger displacement than

the same force applied to harder tissue. By measuring the tissue displacement induced by compression, it is possible to estimate the tissue hardness and to differentiate benign (soft) from malignant (hard) lesions. This relationship between stress (s) and strain (e) is given by Young's modulus or elasticity (E):

$$E = s/e$$

E is larger in hard tissues and lower in soft tissues.

Visually, the elasticity of a tissue is represented by color spectrum. The color given to hard lesions is determined by the manufacturer of the equipment and can be set by the user. Just as in using color Doppler, the user needs to look at the color bar (see Figs. 3-19 and 3-20) to know what colors represent “hard” and “soft” lesions.

Three-Dimensional Scanning

3D scanning has been used extensively in obstetrics and gynecology but so far has limited application in urology. 3D scanning produces a composite of images (data set), which can be manipulated to generate additional views of the anatomy in question (Fig. 3-21).

Figure 3-21. Three-dimensional image of the testis demonstrating intratesticular blood flow on power Doppler. The image can be virtually rotated and manipulated to produce unique anatomic perspectives. (Used with permission by BK Medical, Peabody, MA.)

3D rendering may be important in procedural planning and precise volumetric assessments (Chani et al, 2008a, 2008b). 3D scanning may allow the recognition of some tissue patterns that would otherwise be unapparent on two-dimensional scanning (Mitterberger et al, 2007b; Onik and Barzell, 2008).

CONTRAST AGENTS IN ULTRASONOGRAPHY

Intravenous compounds that contain microbubbles have been used for enhancing the echogenicity of blood and tissue. Microbubbles are distributed in the vascular system and create strong echoes with harmonics when struck by sound waves. The bubbles themselves are rapidly degraded by their interaction with the sound waves. Contrast agents may be useful in ultrasonography of the prostate by enhancing the ability to recognize areas of increased vasculature. The use of intravenous ultrasound contrast agents is considered investigational but has shown promise in numerous urologic scanning situations (Mitterberger et al, 2007a; Wink et al, 2008).

DOCUMENTATION AND IMAGE STORAGE

Documentation is essential for insuring high-quality patient care. Proper documentation includes the production of a permanent record of the ultrasound examination and interpretation of the examination. This documentation is inclusive of the report and acquired images (American Institute of Ultrasound in Medicine, 2009). All documentation must be retrievable and comply with local, state, and federal requirements.

Report

The report should include specific information, including patient identification details, the date of the examination, and the measurement parameters and a description of findings of the examination. Ideally, the report should also include specifics on how the evaluation was performed, including the transducer used, machine used, and settings employed. Most of these details should be on the recorded image that is also stored with the report. The report must be signed by the physician who performed the ultrasound examination, and the indications for performing the examination should be prominently displayed at the top of the report.

Description of ultrasound images

The liver is used as a benchmark for echogenicity:

- Hypoechoic = darker
- Hyperechoic = brighter and white
- Isoechoic = similar to reference point of liver
- Anechoic = black, without echoes

Figure 3-22. Nomenclature for describing the appearance of ultrasound images.

Figure 3-23. In this sagittal image of the right testis, the superior pole of the testis (A) is to the left, the inferior pole of the testis (B) is to the right. The anterior aspect of the testis (C) is at the top of the image, and the posterior aspect (D) is at the bottom. Without the label, there would be no way to distinguish the right from the left testis.

When urologists perform and interpret ultrasound studies, it is important that appropriate nomenclature be used to describe the objects imaged (Fig. 3-22). By convention, the liver is used as a benchmark for echogenicity. If a structure is hypoechoic, it means it is darker than the surrounding tissues. If it is hyperechoic, it means it is brighter than the surrounding tissues. If a structure is isoechoic, it is similar to the surrounding tissues. Structures that do not generate echoes are called *anechoic*. A simple cyst is an example of a structure with an anechoic interior. In general, a high fat content causes tissue to appear hyperechoic, and a high water content causes tissue to appear hypoechoic.

Images

Images should include patient identification details, the date and time of each image, and clear image orientation. Measurements should also be clearly identified with labeling of anatomy and any abnormalities. The image should be able to be interpreted by any appropriately trained sonographer and demonstrate a clear, unimpeded ultrasound image of the anatomy of interest. Images should always be attached to the report or be easily accessible from the report.

By convention, structures imaged by ultrasonography should be oriented so that the superior aspect of the structure is to the left as the image is viewed and the inferior aspect of the structure to the right. With paired structures, it is critical to document right or left. It is useful to use equipment-generated icons to illustrate patient position and the orientation of insonation (Fig. 3-23).

The appropriate number of images to be captured for documentation is the number necessary to document a systematic and complete examination and to document relevant pathology.

Report and Image Storage

The use of electronic medical records has made the documentation of ultrasound examinations easier. However, it has also created challenges in the archiving of images for easy reviewing. These images can occupy large portions of digital storage, and because they are part of the medical record and contain protected health information, they must comply with local, state, and federal regulations. Many validated systems are available for both small and large practices that meet current regulatory requirements.

PATIENT SAFETY

Diagnostic ultrasonography transmits energy into the patient that has the potential to produce biologic effects. The two main categories of biologic effects are **mechanical effects** and **thermal effects**.

The mechanical effects of ultrasonography are torque and streaming. The mechanical effects of an acoustic field may produce a phenomenon called *cavitation*. **Cavitation** occurs when small gas-filled bubbles form and then collapse. These collapsing bubbles liberate a large amount of energy, which may cause damage to tissue in certain circumstances. Mechanical effects are most likely to be observed around gas-containing structures such as lung and bowel.

The thermal effects of ultrasonography are primarily the result of tissue heating resulting from the absorption of energy. The amount of tissue heating is influenced by several factors, including beam focusing, transducer frequency, exposure time, scanning mode, and tissue density.

To assist the sonographer in monitoring the biologic effects of ultrasonography, the **output display standard (ODS)** has been adopted. Two values are typically displayed: the **mechanical index (MI)** and the **thermal index (TI)**. These indices are calculated estimates of the potential for biologic effects of ultrasonography based on the mode of ultrasonography being used, frequency, power output, and time of insonation. The MI indicates the probability that cavitation will occur. For tissues not containing stabilized gas bodies (lung and intestine), the risk of cavitation is low as long as the MI is less than or equal to 0.7. For structures adjacent to lung or intestine, scanning time should be limited if the MI exceeds 0.4. The TI indicates the probability that tissue temperature within the sonographic field will be increased by 1°C. Although the precise consequences of tissue heating are not completely understood, tissue temperature elevations of up to 6°C are not likely to be dangerous unless exposure time exceeds 60 seconds. TI values should be less than 2 for most urologic ultrasound studies (Nelson et al, 2009). The MI and TI are typically displayed on the monitor during ultrasound examinations, and all practitioners should be familiar with the location. **These indices are not safety limits.**

Ultrasonography performed by urologists generally has a low risk for patient harm as long as standard protocols are followed (Rumack et al, 2005). Although tissue heating may occur, there are no confirmed biologic effects of tissue heating in nonfetal scanning except when heating is sustained for extended periods. Users should be aware that for soft tissues not known to contain gas bodies, there is no basis in present knowledge to suggest an adverse nonthermal biologic effect from current diagnostic instruments not exceeding the U.S. Food and Drug Administration output limits (Rumack et al, 2005). Nevertheless, all urologists should endeavor to follow the principles of **ALARA**, which stands for “**As Low As Reasonably Achievable**.” The ALARA principle is intended to limit the total energy imparted to the patient during an examination. This limitation can be accomplished by (1) keeping power outputs low, (2) using appropriate scanning modes, (3) limiting examination times, (4) adjusting focus and frequency, and (5) using the sine function during documentation.

Ultrasound scanning offers an excellent, cost-effective modality for diagnosing and treating urologic conditions. **The most important factor in ultrasound safety is an informed operator.**

Urologists should endeavor to perform limited examinations using consistent technique for specific indications. Patient safety and equipment maintenance should be emphasized in all environments where ultrasound technology is used.

CLINICAL UROLOGIC ULTRASONOGRAPHY

The use of ultrasonography in urology has expanded dramatically because of its profound utility in the clinic and operating room. Long the mainstay of the diagnosis of prostatic disease, ultrasonography is increasingly being used by urologists in the clinical environment for initial diagnosis, interventional management, and longitudinal follow-up of urologic diseases.

Renal Ultrasonography

Urologists, by virtue of their intimate knowledge of surgical anatomy of the kidneys and retroperitoneum, are uniquely qualified to perform and interpret selected ultrasound examinations of the abdomen. These skills are relevant in both the office and the operating room environment. Urologists generally perform abdominal ultrasonography for a specific clinical indication and less often for general screening of the abdominal contents. In most clinical situations, a limited retroperitoneal examination is used in urologic practice.

Technique

The transducer normally used for renal ultrasonography is a curved array transducer of 3.5 to 5.0 MHz. Transducers of a higher frequency may be used for pediatric patients. For intraoperative and laparoscopic renal ultrasonography, a linear array transducer of 6 to 10 MHz is typically employed.

Scanning of the right kidney is performed with the patient supine. The kidney is located by beginning in the midclavicular line in the right upper quadrant. In the sagittal plane, the transducer is moved laterally until the midsagittal plane of the kidney is imaged. After the kidney has been imaged anteriorly and posteriorly in the sagittal plane, the probe is rotated 90 degrees counterclockwise. The midtransverse plane demonstrates the renal hilum containing the renal vein. The kidney is scanned from upper pole to lower pole.

The technique and documentation for left renal ultrasonography are identical to right renal ultrasonography. However, the left kidney is slightly more cephalad than the right kidney. Bowel gas is more problematic on the left because of the position of the splenic flexure of the colon. Visualization of the left kidney often requires the patient to be turned into a lateral position. Ultrasound imaging of the left kidney lacks the liver as an acoustic window, and it is sometimes more difficult to image the left kidney in a true sagittal plane.

Indications

1. Assessment of renal and perirenal masses
2. Assessment of the dilated upper urinary tract
3. Assessment of flank pain during pregnancy
4. Evaluation of hematuria in patients who are not candidates for intravenous pyelography, computed tomography, or magnetic resonance imaging because of renal insufficiency, allergy to contrast media, or physical impediment
5. Assessment of the effects of voiding on the upper urinary tract
6. Evaluation for and monitoring of urolithiasis
7. Intraoperative renal parenchyma and vascular imaging for ablation of renal masses
8. Percutaneous access to the renal collecting system
9. Guidance for transcutaneous renal biopsies, cyst aspiration, or ablation of renal masses
10. Postoperative evaluation of patients after renal and ureteral surgery
11. Postoperative evaluation of patients with renal transplants

Figure 3-24. A, The lower pole of the kidney is displaced 15 degrees laterally compared with the upper pole. B, The kidney is rotated 30 degrees posterior to the true coronal plane. The lower pole of the kidney is slightly anterior compared with the upper pole.

Normal Findings

It is helpful during scanning of the kidney to understand its anatomic position within the retroperitoneum. This understanding assists identifying the midsagittal plane, which serves as a reference point for a complete examination (Fig. 3-24).

The adult right kidney in the sagittal view demonstrates a cortex that is usually hypoechoic with respect to the liver. The central band of echoes in the kidney is a hyperechoic area that contains the renal hilar adipose tissue, blood vessels, and collecting system. Acoustic shadowing from ribs overlying the inferior pole can be eliminated by moving the probe to a more lateral position or into the intercostal space. By having the patient take a deep breath, the kidney can be moved inferiorly to assist complete imaging (Fig. 3-25).

The echogenicity of the kidney varies with age. The renal cortex of an infant is relatively hyperechoic compared with that of an adult. In addition, there is a smaller and less apparent central band of echoes in the infant. In the adult, the echogenicity of the renal cortex is usually hypoechoic with respect to the liver (Emamian et al, 1993). In patients with chronic renal diseases, the renal cortex is often thinned and isoechoic or hyperechoic with respect to the liver (O'Neill, 2001).

Renal size changes over the lifetime of an individual. Nomograms for pediatric renal size should be consulted; these are based on age, height, and weight of the patient. The average adult kidney measures 10 to 12 cm in length and 4 to 5 cm in width. Measurements of renal volume may be appropriate in cases of severe renal impairment. Renal measurements should be obtained in the midsagittal plane and midtransverse plane. Measurements taken in other than the midsagittal plane and midtransverse plane may be spuriously low. The thickness of the parenchyma is the average distance between the renal capsule and the central band of echoes. The precise location for making this measurement is subjective. The midlateral renal parenchyma in the sagittal view is a common choice for obtaining this measurement (Fig. 3-26). Although there is no universal standard, the renal cortical thickness should be greater than 7 mm (Roger et al, 1994), and the renal parenchymal thickness should be greater than 15 mm in adults (Emamian et al, 1993).

Doppler ultrasound may be helpful in evaluating the renal artery and renal vein and assessing the vascular resistance in the kidney. Doppler modes may also be useful in evaluating neovascularity associated with renal tumors and in correctly characterizing hypoechoic structures in the renal pelvis, such as a parapelvic cyst, the renal vein, or the dilated collecting system.

Procedural Applications

Percutaneous renal biopsy has been performed as an office procedure by several groups for the past 2 decades and found to be a safe and effective procedure (Christensen et al, 1995; Fraser and Fairley, 1995; Hergesell, 1998). In a series of 131 ultrasound-guided

Figure 3-25. Midsagittal plane of the kidney. Note the relative hypoechoic nature of the renal pyramids (P) compared with the cortex (C). The central band of echoes (B) is hyperechoic compared with the cortex. The midsagittal plane has the greatest length measurement pole to pole. A perfectly sagittal plane results in a horizontal long axis of the kidney.

Figure 3-26. The distinction between renal cortical thickness and renal parenchymal thickness is that the renal parenchyma is measured from the central band of echoes to the renal capsule. The renal cortex is measured from the outer margin of the medullary pyramid to the renal capsule.

biopsies by Christensen and colleagues (1995), complications occurred in 21% of patients (18% minor complications and 3% major complications). In their series, increasing the number of biopsy passes did not increase the complication rate, whereas the presence of severe hypertension did. Fraser and Fairley (1995) compared 118 outpatient ultrasound-guided biopsies with 232 inpatient procedures and found no difference in complication rate. Hergesell (1998) reviewed a series of 1090 percutaneous biopsies performed with local anesthesia and ultrasound guidance. Only one case required interventional radiology for persistent blood loss, 2.2% (25 of 1090) of cases had minor hematoma that was conservatively treated, and self-limited macrohematuria was found in 0.8% (9 of 1090) of cases. In a subset of the population evaluated by Doppler ultrasonography, hemodynamically irrelevant arteriovenous fistula was found in 9% (48 of 533) of cases. Sufficient tissue was obtained in 98.8% of cases.

Al-Hweish and Abdul-Rehman (2007) followed two groups. Patients in group I ($n = 22$) had a 24-hour hospital admission after the biopsy, and patients in group II ($n = 22$) were observed for 6 hours after the biopsy and then discharged. A small perinephric hematoma that resolved spontaneously was observed in a single patient in group II. Gross hematuria (13.6% in group I and 9.1% in group II) was the only significant complication observed and occurred in all cases within 6 hours.

The safety and efficacy of outpatient percutaneous renal biopsy have also been reported for pediatric patients (Davis et al, 1998; Kamitsuji et al, 1999; Hussain et al, 2003) and elderly patients (Kohli et al, 2006; Stratta et al, 2007; Moutzouris et al, 2009).

Limitations

Some patients are not favorable candidates for renal ultrasonography. Obesity, intestinal gas, and physical deformity may be impediments to complete renal evaluation. Renal ultrasonography has poor sensitivity for renal masses less than 2 cm (Warshauer et al, 1988). There is a lack of specificity for renal tumor type except for angiomyolipoma. Angiomyolipoma has characteristics that are distinctive on ultrasonography (highly echoic), but some small renal cell carcinomas have been shown to be indistinguishable from angiomyolipoma by ultrasound criteria (Yamashita et al, 1992; Forman et al, 1993).

Transabdominal Pelvic Ultrasonography

Transabdominal pelvic ultrasonography is a tremendously versatile tool for the urologist. It is a noninvasive method for evaluating the lower urinary tract and prostate in men and the bladder in women. A curved array transducer of 3.5 to 5 MHz is most commonly employed to perform transabdominal ultrasonography. In pediatric

patients, a higher frequency transducer may be used. In cases in which only a residual urine or bladder volume is to be determined, an automated bladder scanner is often employed.

Technique

Bladder ultrasonography is most commonly performed with the patient supine and the sonographer on the patient's right side. The scan should be performed in a warm room, and the patient should be draped to provide for comfort and privacy. If necessary, a roll may be placed beneath the patient's hips. The scanning technique depends on the circumstances and the reason for the examination, but in general the scan should be performed with a moderately filled bladder. The bladder should be scanned in a sagittal and transverse manner angling the probe into the pelvis so that the bladder can be visualized beneath the pubic bone. Although the prostate cannot be imaged with the same resolution achieved during transrectal scanning, the size and morphology of the prostate can be demonstrated. Although transabdominal scanning is the most common means of evaluating the bladder, the bladder may also be assessed using transvaginal and transrectal approaches. These approaches are useful in patients who are obese or who are not suitable candidates for transabdominal scanning.

Indications

1. Measurement of bladder volume or postvoid residual urine
2. Assessment of prostate size and morphology
3. Demonstration of secondary signs of bladder outlet obstruction
4. Evaluation of bladder wall configuration and thickness
5. Evaluation of hematuria of lower urinary tract origin
6. Detection of ureterocele
7. Assessment for ureteral obstruction
8. Detection of perivesical fluid collections
9. Evaluation of clot retention
10. Confirmation of catheter position
11. Removal of retained catheter
12. Guidance of suprapubic tube placement
13. Establishment of bladder volume before and after flow rate determination

Normal Findings

Transabdominal pelvic ultrasonography should include evaluation of the lumen of the bladder and bladder wall configuration and thickness. The presence of specific lesions such as stones or tumors should be documented. The structures immediately surrounding the bladder may also be evaluated, including the distal ureters, the prostate in men, and the uterus and ovaries in women (Fig. 3-27).

Figure 3-27. A, Transverse view of the bladder (BL) in a female patient demonstrates the uterus (U). B, Sagittal view of the bladder shows the uterus posterior to the bladder.

The emergence of urine from the ureteral orifices (ureteral jets) can be demonstrated. The clinical value of demonstrating ureteral jets has been questioned. To verify the absence of a ureteral jet, 10 minutes of continuous observation may be required (Fig. 3-28) (Delair and Kurzrock, 2006).

Bladder volume can be calculated manually by obtaining measurements in the midtransverse plane and midsagittal plane (Fig. 3-29). Numerous studies have shown that for bladder volumes of 100 to 500 mL, such calculated volumes are within 10% to 20% of the actual bladder volume (Simforoosh et al, 1997; Ghani et al, 2008b; Park et al, 2011). Measuring bladder wall thickness may assist the clinician in understanding the degree of bladder outlet obstruction (Fig. 3-30). Bladder wall thickness varies depending on the volume of urine in the bladder and on which part of the bladder wall is measured. It has been shown that measuring bladder wall thickness may predict bladder outlet obstruction with greater accuracy than free uroflowmetry, postvoid residual urine, and prostate volume (Oelke et al, 2007).

Transabdominal ultrasonography of the prostate requires angling the probe beneath the pubic bone. In the transverse plane, the transducer is fanned inferiorly until the largest transverse diameter of the prostate is identified. Measurements of the transverse width and height are obtained (Fig. 3-31A). The transducer is then rotated 90 degrees clockwise to produce a true sagittal image of the

prostate. The transducer is fanned until the midline is identified; this is recognized by a V-shaped indentation at the bladder neck (Fig. 3-31B). Depending on the degree of prostatic hypertrophy and the presence or absence of a middle lobe, this V may be more or less apparent and more or less anterior or posterior in its position. A sagittal measurement is made from the bladder neck to the apex of the prostate. The apex of the prostate may be identified by using the hypoechoic urethra as a guide.

The degree of protrusion of the prostate into the bladder may have some predictive value for bladder outlet obstruction. It has been shown that intravesical prostatic protrusion correlates well with formal urodynamic evaluation of bladder outlet obstruction (Chia et al, 2003; Keqin et al, 2007). The measurement is obtained by drawing a line corresponding to the bladder base on a sagittal scan and measuring the perpendicular distance from bladder base to greatest protrusion of the prostate into the bladder (Fig. 3-32).

Transabdominal ultrasonography of the prostate is useful in characterizing prostatic urethral length, the size and configuration of the middle lobe of the prostate, and some secondary information about the physiology of bladder outlet obstruction. This information is valuable in treatment planning for bladder outlet obstruction.

Procedural Applications

Transabdominal ultrasound-guided percutaneous bladder aspiration with or without catheter placement has been successfully used in neonates, children, and adults (Gochman et al, 1991; Wilson and Johnson, 2003). It has also been employed for treatment of bladder stones (Ikari et al, 1993; Sofer et al, 2004). Ultrasound-guided aspiration has also been used for peritoneal drainage after bladder perforation (Manikandan et al, 2003).

Limitations

Transabdominal pelvic ultrasonography yields limited information in patients with an empty bladder. The ability to identify distal

Figure 3-28. In this transverse view of the bladder, urine “jets” emerging from the left (arrow) and right (arrowhead) ureteral orifices are demonstrated by power Doppler.

Figure 3-29. Measurement of bladder volume using the formula: bladder volume = width (transverse plane) × height (transverse plane) × length (midsagittal plane) × 0.625. In the sagittal plane, the dome (D) of the bladder is to the left, and the prostate (P) is to the right.

Figure 3-30. Bladder wall thickness may provide information about bladder outlet obstruction. In this sagittal view, bladder wall thickness is measured posteriorly (arrow) near the midline. Note the trabeculation of the relatively hyperechoic bladder wall.

Figure 3-31. A, Transabdominal ultrasonography is extremely useful for measuring prostatic volume and evaluating prostatic morphology. The volume of the prostate can be calculated using the formula: prostate volume (mL) = width (cm) × height (cm) × length (cm) × 0.523. B, In this midsagittal view of the prostate (P), the bladder neck is identified as a V-shaped indentation (arrow). Note the characteristically hyperechoic trigone (arrowhead).

Figure 3-32. In this sagittal view of the prostate, the middle lobe extends into the bladder (A). The bladder base is defined by the line B. The length of line A is the intravesical prostatic protrusion.

ureteral obstruction, bladder stones, and bladder tumors requires a full bladder. Although prostatic morphology and volume can be assessed with an empty bladder, it is much easier when the bladder is full. Pelvic structures may be difficult to evaluate in patients with a protuberant abdomen or panniculus. **Although ultrasonography is used, automated measurement of bladder volume or residual urine is not an imaging study.** Lack of imaging confirmation can lead to inaccurate residual urine determinations in patients with obesity, clot retention, ascites, bladder diverticulum, or perivesical fluid collection (e.g., urinoma, lymphocele).

Ultrasonography of the Scrotum

No aspect of urologic care is better suited to the use of ultrasonography than evaluation of the scrotum. Urologists have a surgical understanding of the anatomy and extensive experience with the diagnosis and treatment of disorders that affect the scrotum. Because the scrotum and its contents are superficial, high-frequency transducers may be employed to yield excellent and detailed anatomic and physiologic information. Imaging information can be correlated with findings on direct physical examination.

Technique

Sound technique is critical to performing adequate ultrasonography of the scrotum. In general, the examination should be carried out in a quiet room that is adequately warm for patient comfort. The patient should be supine with the scrotum supported on a towel or on the anterior thighs. The patient should be draped in such a way as to hold the penis out of the way and to ensure patient privacy. Copious amounts of conducting gel should be used to provide a good interface between the transducer and the scrotal skin because air trapping by scrotal hair results in unwanted artifacts. Complete but gentle contact between skin and transducer is essential because excessive pressure results in movement of testis or compression of the testis. Compression may change echogenicity and obscure fine anatomic detail. In addition, compression may significantly alter volume measurements.

Scrotal ultrasonography is performed with a high-frequency linear array transducer, generally in the range of 7 to 18 MHz. Transducers may be 4 to 7.5 cm in width. Some sonographers prefer the maneuverability of a 4-cm transducer, whereas others prefer the longer 7.5-cm transducer for its ability to image the entire testis simultaneously in the sagittal plane. Imaging should be done in a systematic fashion and should include sagittal and transverse views of the testis. The sagittal view should proceed from the midline medially and then laterally and from the midtransverse section of the testis to the upper pole and the lower pole of the testis. In addition to the testis, the epididymis and entire scrotal contents should be imaged.

Indications

1. Assessment of scrotal and testicular mass
2. Assessment of scrotal and testicular pain
3. Evaluation of scrotal trauma
4. Evaluation of infertility
5. Follow-up of scrotal surgery
6. Evaluation of empty or abnormal scrotum

Normal Findings

It is important to document the size and, if appropriate, the volume of the testes. The echo architecture of the testis should be described (Fig. 3-33). It is important to compare the testes for echogenicity because some infiltrative processes may result in diffuse changes in a testis that would be noticed only when that testis is compared with its contralateral mate (Fig. 3-34). For example, lymphomatous or leukemic involvement of the testis may result in a diffusely hypoechoic and homogeneous appearance, which may be unilateral (Mazzu et al, 1995). If paratesticular fluid is present, the

epididymis and the testicular and epididymal appendages are more easily identified (Fig. 3-35).

Normal testicular blood flow may be demonstrated with color or power Doppler (Fig. 3-36) (Barth and Shortliffe, 1997). Intratesticular blood flow is low velocity with the average PSV of less than 10 cm/sec (Middleton et al, 1989). Intratesticular blood flow is primarily supplied by the testicular artery, which ultimately divides to supply the individual testicular septa. The fibrous septa coalesce to form the mediastinum testis, which is a hyperechoic linear structure seen in the sagittal plane (Fig. 3-37).

Spectral Doppler is useful in evaluating the intratesticular blood flow with elevated resistive index greater than 0.6 suggestive of impaired spermatogenesis (Fig. 3-38) (Biagiotti et al, 2002; Pinggera et al, 2008; Hillelsohn et al, 2013).

Procedural Applications

The testis lends itself to easy access for ultrasound localization of internal structures and for percutaneous access. In particular, small nonpalpable lesions can be localized by ultrasonography, guiding

Figure 3-33. In this longitudinal view, the head of the epididymis (E) is seen to the left, and the lower pole of the testis is to the right. Normal testicular sonographic anatomy is characterized by a homogeneous, finely granular appearance of the testis.

Figure 3-34. Simultaneous bilateral views are important to rule out a diffuse infiltrative process such as lymphoma. A diffuse and homogeneous change in echogenicity in one testis could otherwise be unappreciated. In this example, the testes are symmetric and normal. This view is also required to document the presence of two testes.

Figure 3-35. The presence of paratesticular fluid (F) permits the identification of the appendix epididymis (A) and the appendix testis (B).

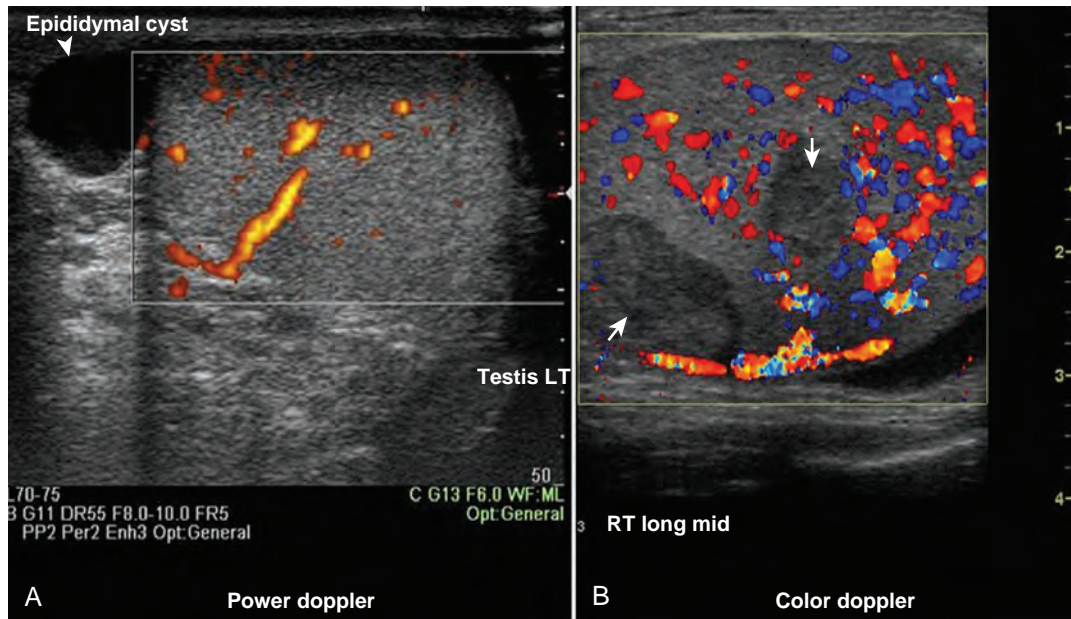

Figure 3-36. A, Normal intratesticular blood flow by power Doppler; note the epididymal cyst (arrowhead). B, Increased blood flow in an irregular pattern demonstrated by color Doppler was associated with necrotizing vasculitis; note the relatively hypoechoic areas of decreased vascularity (arrows).

Figure 3-37. Sagittal image of this testis demonstrates a common anatomic finding, the hyperechoic mediastinum testis (arrows). The mediastinum testis is a normal structure resulting from the coalescence of the fibrous septa of the testis.

placement of a needle for percutaneous biopsy or injection of a dye for localization during open biopsy (Buckspan et al, 1989).

Current therapeutic applications using ultrasound guidance include percutaneous testicular sperm aspiration (Friedler et al, 1997; Belker et al, 1998; Khadra et al, 2003) and percutaneous epididymal sperm aspiration (Craft et al, 1995; Belker et al, 1998; Levine and Lisek, 1998; Meniru et al, 1998; Rosenlund et al, 1998; Lin et al, 2000; Pasqualotto et al, 2003). Future ultrasound-guided applications might include spermatogonia stem cell transfer to testes devoid of germ cells after gonadotoxic therapies.

Sonoelastography

Two more recent studies used real-time elastography to differentiate benign from malignant testicular lesions because it is postulated

Figure 3-38. Spectral Doppler analysis of an intratesticular artery demonstrating a peak systolic velocity of 5.3 cm/sec, an end-diastolic velocity of 1.94 cm/sec, and a calculated resistive index of 0.63 in a patient with dyspermia.

that malignant lesions have an increased stiffness secondary to a higher concentration of vessels and cells compared with surrounding tissues. Goddi and colleagues (2012) assessed 88 testes with 144 lesions and found a 93% positive predictive value, 96% negative predictive value, and 96% accuracy (see Fig. 3-19). Aigner and associates (2012) assessed 50 lesions and found a 92% positive predictive value, 100% negative predictive value, and 94% accuracy in differentiating malignant from benign lesions. Additionally, Li and coworkers (2012) found that men with non-obstructive azoospermia had significantly different testicular elasticity compared with patients with obstructive azoospermia and healthy controls with a normal semen analysis. Real-time tissue

elastography (see Fig. 3-20) is an exciting new innovation in assessing abnormalities on scrotal examination; however, more data are necessary before surgical intervention can be safely avoided based on the findings.

Limitations

Caution should be used when interpreting Doppler flow studies in the evaluation of suspected testicular torsion. The hallmark of testicular torsion is the absence of **intratesticular** blood flow (Fig. 3-39). Paratesticular flow in epididymal collaterals may appear within hours of torsion. Comparison with the contralateral testis should be performed to ensure that the technical attributes of the study are adequate to demonstrate intratesticular blood flow.

Ultrasonography of the Penis and Male Urethra

Ultrasonography of the penis and male urethra provides exquisite anatomic detail and may be used in many cases in lieu of studies requiring ionizing radiation.

Technique

Penile and urethral ultrasonography is best performed with a 12- to 18-MHz linear array transducer for optimal resolution. The technique for penile and urethral ultrasonography includes imaging the phallus in the longitudinal and transverse planes. Both ventral and dorsal surfaces of the phallus can be interrogated. Similar to scrotal ultrasonography, the examination is best carried out in a quiet room that is adequately warm for patient comfort. Draping is done to ensure patient privacy. The examination is performed in a systematic fashion beginning at the base of the penis and proceeding distally to the glans. It is possible to obtain an image of the proximal urethra and corporeal bodies by scanning through the scrotum or the perineum.

It may be helpful when evaluating the penile urethra, especially for stricture disease, to inject a sterile gel into the urethra in a retrograde fashion. The gel distends the urethra and allows better identification of urethral anatomy and the anatomy of the corpus spongiosum.

Indications

1. Evaluation of penile vascular dysfunction
2. Documentation of fibrosis of the corpora cavernosa
3. Localization of foreign body
4. Evaluation of urethral stricture
5. Evaluation of urethral diverticulum
6. Assessment of penile trauma or pain

Normal Findings

Scanning of the external portion of the phallus can be performed either from the dorsal or from the ventral surface (Fig. 3-40). Transverse scanning of the phallus reveals the two corpora cavernosa dorsally and the urethra ventrally. The sagittal view of the phallus demonstrates the corpora cavernosa with a hyperechoic, double linear structure representing the cavernosal artery (Fig. 3-41). The corpus spongiosum is isoechoic to slightly hypoechoic and contains the coapted urethra. The urethra is collapsed except during voiding.

Perineal Ultrasonography

The more proximal aspects of the urethra and corpora cavernosa are best assessed through a perineal approach by placement of the transducer on the perineum. The bulbar urethra with the bulbar branch of the pudendal artery and the proximal cavernosal bodies and the cavernosal branch of the pudendal artery can be visualized (Fig. 3-42).

Transperineal and translabial ultrasonography has also been used for evaluation of the pelvic floor for both diagnostic purposes and postprocedural follow-up. The anterior, central, and posterior compartments are well visualized. In contrast to a transvaginal approach, this approach is noninvasive and does not distort the pelvic anatomy (Baxter and Firoozi, 2013).

Procedural Applications

The most common application of penile ultrasonography is in the evaluation of erectile dysfunction and penile curvature. Pharmacostimulation provides quantification of cavernosal artery blood flow velocity (Fig. 3-43). Primary criteria for arteriogenic erectile

Figure 3-39. Demonstration of normal bilateral intratesticular blood flow by color Doppler.

Figure 3-40. Transverse view of the phallus with the transducer placed either on the dorsal or the ventral surface. Note the compression of the urethra and corporal spongiosum compression in the ventral projection with minimal pressure applied to the phallus. CC, corpora cavernosa.

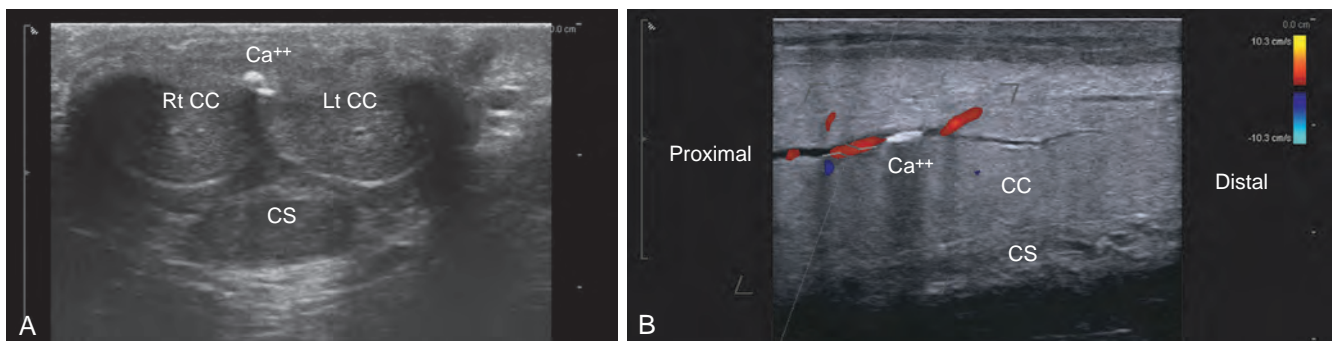

Figure 3-41. A, In the transverse plane scanning from the dorsal surface of the midshaft of the penis, the corpora cavernosa (CC) are paired structures seen dorsally, whereas the corpus spongiosum (CS) is seen ventrally in the midline. A calcification (Ca^{++}) is seen between the two CC with posterior shadowing. B, In the parasagittal plane, the corpus cavernosum (CC) is dorsal with the relatively hypoechoic CS seen ventrally. Within the CC, the cavernosal artery is shown with a calcification (Ca^{++}) in the wall of the artery and posterior shadowing.

Figure 3-42. The internal pudendal artery gives rise to the bulbourethral artery, dorsal artery, and cavernous artery. The most proximal aspect of the cavernous artery is best imaged through the perineum. (From Gilbert BR. *Ultrasound of the male genitalia*. New York: Springer. In press.)

dysfunction include a PSV less than 25 cm/sec, cavernosal artery dilation less than 75%, and acceleration time greater than 110 msec. In cases of equivocal PSV measurements, particularly when PSV is between 25 cm/sec and 35 cm/sec, additional criteria are asymmetry of greater than 10 cm/sec in PSV comparing the two cavernosal arteries, focal stenosis of the cavernosal artery, and cavernosal-spongiosal flow reversal (Benson et al, 1993).

In addition, arteriogenic erectile dysfunction has been found to correlate directly with other systemic cardiovascular diseases,

including coronary artery disease and peripheral vascular disease, in many population studies. PSV is the most accurate measure of arterial disease as the cause of erectile dysfunction. The average PSV after intracavernosal injection of vasoactive agents in healthy volunteers without erectile dysfunction ranges from 35 to 47 cm/sec, with a PSV of 35 cm/sec or greater signifying arterial sufficiency after pharmacostimulation (Lue et al, 1985; Mueller and Lue, 1988; Benson and Vickers, 1989; Shabsigh et al, 1990; Broderick and Lue, 1991; Pescatori et al, 1994; Schaeffer et al, 2006). The first indication of vascular disease often can be the penile cavernosal artery being less than 1 mm. The finding of arteriogenic dysfunction can often provide a window of opportunity (Miner, 2011) to identify and potentially to alter the progressive nature of systemic vascular disease (Montorsi et al, 2006; Gazzaruso et al, 2008; Seftel, 2011).

Assessment of penile curvature most often involves palpation and ultrasound interrogation of the phallus after pharmacostimulation. However, a palpable plaque is not easily identified (Prando, 2009; Kalokairinou et al, 2012). In many cases, standard B-mode and color Doppler ultrasound modalities often do not localize pathology. Sonoelastography (tissue elasticity imaging) evaluates the stiffness of biologic tissues and localizes these nonpalpable lesions not visualized on ultrasonography for potential treatment (Fig. 3-44) (Richards et al, 2014).

Limitations

The complete evaluation of the penile urethra, corpora cavernosa, and corpus spongiosum requires a dorsal or ventral interrogation of the exposed phallus and a perineal approach to the nonexposed portions of the phallus; this is particularly important in evaluation of the bulbourethra and proximal corpora. In addition, the evaluation of erectile dysfunction requires qualitative and quantitative measurements of blood flow in the penile arteries. Such evaluation requires blood flow measurements before and after intracavernosal injection of vasoactive substances.

Figure 3-43. Longitudinal view of the right corpora cavernosa demonstrating peak systolic and end-diastolic flow velocity in the right cavernosal artery, which measures 0.89 mm in diameter.

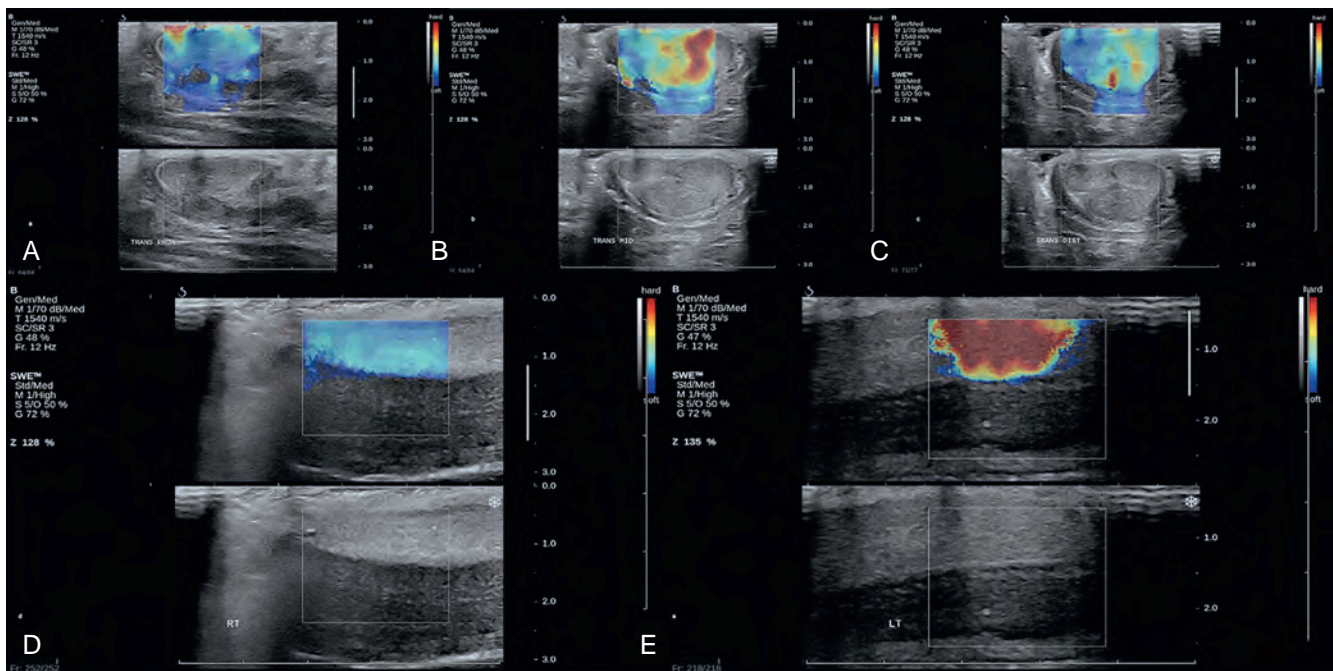

Figure 3-44. Sonoelastograms (scaled with red more firm and blue less firm) superimposed over transverse B-mode ultrasound images of the (A) proximal, (B) mid and (C) distal phallus. Sonoelastograms superimposed over parasagittal views of the (D) right and (E) left cavernosal bodies. (From Richards G, Goldenberg E, Pek H, Gilbert BR. Penile sonoelastography for the localization of a non-palpable, non-sonographically visualized lesion in a patient with penile curvature from Peyronie's disease. *J Sex Med* 2014;11:516–20.)

Transrectal Ultrasonography of the Prostate

TRUS of the prostate is the sonographic imaging procedure most commonly performed by urologists (Trabulsi et al, 2013). It is minimally invasive and provides exquisite anatomic detail of the prostate and periprostatic tissues. An overview is presented here of transrectal prostate imaging. A comprehensive discussion is provided in Chapter 109. TRUS performed by the urologist enhances patient care by providing a minimally invasive procedure that gives real-time information for a rapid and accurate diagnosis.

Technique

A systematic scan insures that a comprehensive examination is performed and appropriately documented. A high-frequency 7.5- to 10-MHz transducer is usually used. This can be a biplanar or single-plane transducer (i.e., “end fire” or “side fire”).

It is essential to perform a digital rectal examination **before** inserting the ultrasound probe. Pain or tenderness, rectal stricture, mass, lesion, or bleeding that is encountered when performing the rectal examination or when inserting the probe might preclude TRUS.

After probe insertion, a “survey” scan is performed of the prostate from base to apex including the seminal vesicles and rectal wall. The seminal vesicles are then examined in the transverse plane for comparative evaluation of echogenicity and measurements of seminal vesicle height and ampulla (vas deferens) diameter. Next, the midsagittal transverse and longitudinal image of the prostate is examined, and anteroposterior, height, and length measurements are taken. Prostate volume, predicted prostate-specific antigen (PSA), and PSA density can be calculated usually by formulas already programmed in the ultrasound machine. As in many urologic applications of sonography, color Doppler can add valuable information.

The rectal wall thickness must be evaluated and documented as well as any other notable findings (Trabulsi et al, 2013). Rectal cancer, polyps, and inflammatory processes require further evaluation. The appearance of rectal abnormalities should be documented, and a referral may need to be made.

Indications

1. Measurement of prostate volume for determination of PSA density
2. Abnormal digital rectal examination
3. Prostatic assessment with sonographic controlled biopsy
4. Cysts
5. Evaluation for and aspiration of prostate abscess
6. Assessment for suspected congenital abnormality
7. Lower urinary tract symptoms
8. Pelvic pain
9. Prostatitis or prostatic dysplasia
10. Hematospermia
11. Infertility (e.g., azoospermia)
 - a. Low volume or poorly motile specimen
 - b. Cysts
 - c. Hypoplastic or dilated seminal vesicle
 - d. Impaired motility
 - e. Antisperm antibodies

Normal Findings

Echogenicity is best evaluated by comparing the left and right sides of the prostate (Fig. 3-45). In a young man, TRUS is often indicated in the evaluation of subfertility. The young male prostate is homogeneous with zones often difficult to visualize. The “sonographic capsule” can be identified because of the impedance difference between the prostate and surrounding fat. The prominence of the urethra (“u” in Fig. 3-45) is related to the surrounding low reflectivity of urethral muscles. In the young male prostate,

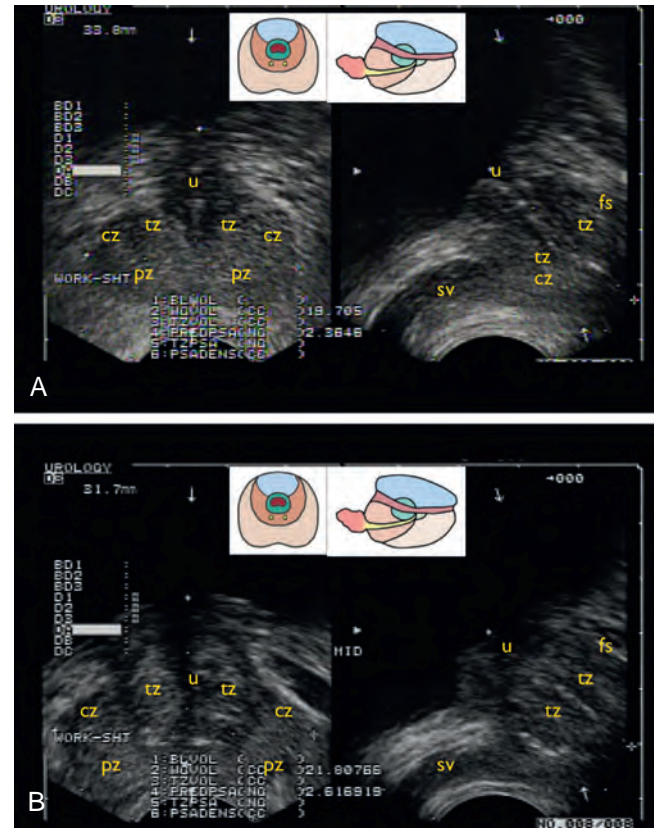

Figure 3-45. A, Young male prostate. The peripheral zone (pz) is often hyperreflective to the central (cz) and transition (tz) zones. The cz and tz are difficult to differentiate from each other, and the fibromuscular stroma (fs) is positioned anterior to the urethra. B, Older male prostate. The glandular and stromal elements enlarge increasing the size of the tz and occasionally pz. The tz is seen independent of other zones, and the cz is difficult to visualize.

the peripheral zone (“pz” in Fig. 3-45) is often hyperreflective to the central and transition zones (“cz” and “tz” in Fig. 3-45). The central and transition zones are difficult to differentiate from each other, and the fibromuscular stroma (“fs” in Fig. 3-45) is positioned anterior to the urethra. In an older man, the glandular and stromal elements enlarge increasing the size of the transition zone and occasionally the peripheral zone. The transition zone is seen independent of other zones, and the central zone is difficult to visualize.

The base of the prostate is located at the superior aspect of the prostate contiguous with the base of the bladder. The apex of the prostate is located at the inferior aspect of the prostate continuous with the striated muscles of the urethral sphincter.

Procedural Applications

Biopsy of the prostate guided by TRUS is most often initially performed for a specific clinical indication, such as an elevation or change in the PSA or an abnormal digital rectal examination (Porter, 2013). High-grade prostatic intraepithelial neoplasia and atypical small acinar proliferation on an initial biopsy specimen are considered by some clinicians to be indications for immediate or planned repeat biopsy. TRUS biopsy may be performed for an increasing PSA after initial therapy. In the case of a patient with an increasing PSA after radical retropubic prostatectomy, ultrasonography and biopsy of the prostatic fossa and vesicourethral anastomosis may be performed to aid in diagnosis of local recurrence. TRUS biopsy is performed after radiation therapy or cryotherapy to aid in diagnosis of local treatment failure.

Prostatic cyst aspiration is a therapeutic procedure easily performed in the office with minimal patient discomfort. It is often indicated when a large midline cyst obstructs the ejaculatory ducts resulting in dilation of the ejaculatory ducts or seminal vesicles or both. Refilling of the cyst is common.

Limitations

Bowel preparation is sometimes necessary for imaging. In addition, the patient's body habitus might make it difficult to image the base of the prostate, seminal vesicles, and bladder adequately. Current technology limits the diagnostic capabilities of TRUS to anatomic anomalies.

PRACTICE ACCREDITATION

When performing office ultrasonography, urologists must be committed to ensure that equipment, sonographers, and protocols are able to provide high-quality diagnostic information. Likewise, patients rightfully expect that the ultrasound examination performed uses equipment that is safe and can effectively image the organ of interest. In addition, third-party payers have instituted requirements for practices, including urology practices, to follow to be compensated for their work in providing ultrasound imaging services. One way the urologist sonographer ensures that his or her ultrasound examination is compliant with current standards and protocols is through practice accreditation. There are presently two acknowledged accrediting agencies: the American College of Radiology (ACR) and the American Institute for Ultrasound in Medicine (AIUM). The AUA and the AIUM have partnered to develop a pathway whereby urology practices can obtain accreditation that is recognized by regulatory authorities and third-party payers.

There are few laws regulating the performance and interpretation of ultrasound examinations. Any licensed physician may purchase an ultrasound machine and begin performing and interpreting sonograms. To ensure quality of an ultrasound examination, the ACR and the AIUM began to develop programs in 1995 to accredit ultrasound practices, and the two organizations accredited the first ultrasound practices in 1996. As of this writing, there are 4401 practices (each site applies as a single practice) with ACR ultrasound accreditation and 1210 (a total of 2039 sites) with AIUM ultrasound accreditation.

The ACR offers ultrasound practice accreditation in breast, general, gynecologic, obstetric, and vascular ultrasonography. The AIUM offers ultrasound practice accreditation in abdominal/general, breast, dedicated musculoskeletal, dedicated thyroid/parathyroid, gynecologic, fetal echocardiography, obstetric, and more recently urologic ultrasonography.

How does ultrasound practice accreditation differ from AUA board certification? Certification is granted to an individual who has demonstrated a level of knowledge and who continues to meet the requirements necessary to maintain the certification. The individual remains certified regardless of where he or she works. Accreditation is granted to a practice (which may be the practice of a solo practitioner) that demonstrates that all of the individuals in the practice, all the relevant policies and procedures, and equipment and maintenance meet certain requirements. Practices must continue to demonstrate compliance at regular intervals, regardless of whether there are changes in personnel, policies, or equipment. An individual who works in an accredited practice cannot go to another practice and claim that the services provided at the second facility are accredited.

The process of practice accreditation is not without challenges to both the urologists and the urology practice. Urologists have traditionally viewed imaging as a tool, similar to a stethoscope, that assists them in providing care for their patients. The process of accreditation changes this traditional view by requiring both the urologist and the urology practice to expend resources to meet the requirements of accreditation. However, the accreditation process

helps organize the approach to the ultrasound examination and markedly improves quality. This translates into improved diagnostic ultrasound examinations and improved patient care ([Abuhamad and Benacerraf, 2004](#)).

KEY POINTS

- An ultrasound wave is a mechanical wave that creates alternating areas of compression and rarefaction in tissue.
- Axial resolution improves with increasing frequency of the ultrasound wave.
- Depth of ultrasound penetration decreases with increasing frequency.
- Optimal ultrasound imaging requires tradeoffs between resolution and depth of penetration.
- Artifacts may be helpful in the diagnosis of certain conditions.
- The appropriate number of images to be captured for documentation is the number necessary to document a systematic and complete examination and to document relevant pathology.
- The mechanical index and the thermal index are not safety limits.
- The ALARA principle is intended to limit the total energy imparted to the patient during an examination.
- The most important factor in ultrasound safety is the informed operator.
- Angiomyolipoma has a characteristic hyperechoic appearance, but some renal cell carcinomas are also hyperechoic.
- Although ultrasonography is used in automated measurement of bladder volume or residual urine, this is not an imaging study.
- Sonoelastography extends the ability of ultrasonography to detect "hardness" of a lesion.
- The hallmark of testicular torsion is the absence of intratesticular blood flow. However, ultrasonography cannot diagnose torsion—only the surgeon or the pathologist can.

Outcomes Research

Mark S. Litwin, MD, MPH, and Jonathan Bergman, MD, MPH

Access to Care

Costs of Care

Quality of Care

Health-Related Quality of Life

Health Services Research Methodologies

Future Implications

Health services research, often loosely described as *outcomes research*, is the study of the end results of health services, taking into account patient preferences, values, and experiences (Ware, 1984; Clancy and Eisenberg, 1998). It focuses on access to care, cost of care, quality of care, health systems, and population health (Epstein and Sherwood, 1996; Israel et al, 1998; Kane, 2006; Minkler and Wallerstein, 2008).

ACCESS TO CARE

Access to care includes the “actual use of personal health services and everything that facilitates or impedes their use. It is the link between health services systems and the populations they serve” (Aday and Andersen, 1974; Andersen et al, 2002; Andersen and Davidson, 2007). Improving access can reduce mortality, increase self-reported health, and decrease delays in care (Zweifel et al, 2011; Sabik, 2012; Sommers et al, 2012). Variations in access correlate with variable quality, including receipt of preventive care (Radley and Schoen, 2012). As certain aspects of urologic care become centralized, access to care is an increasingly important issue in urology (Stitzenberg et al, 2012).

Andersen presented a behavioral model for considering health care access in which three categories of factors determine how and whether individuals use medical services (Andersen and Davidson, 2007). These include predisposing factors (e.g., health beliefs, attitudes); enabling factors (e.g., health insurance, geographic proximity); and need factors (e.g., the presence of symptoms or diseases) (Northam, 1996; Shaw, 2012). Barriers to health care access often result from financial determinants such as the lack of health insurance or adequate income; logistic challenges in coordinating child care, public transportation, and work schedules; clinic waiting times; and difficulties with the geographic proximity of clinics and hospitals (DeVoe et al, 2007; Carrillo et al, 2011; Parikh et al, 2012). Adequate access requires more than a guarantee of payment for services; even with generous benefits, individuals must navigate nonfinancial barriers. Among these are minority status (Mandelblatt et al, 1999; Rosenbaum et al, 2000; Lurie and Dubowitz, 2007; Barocas et al, 2013a; Dickson et al, 2013; Flores and Lin, 2013); gender (Li et al, 2007; Kullgren et al, 2012; Ghani et al, 2013; Kates et al, 2013); sexual orientation (Buchmueller and Carpenter, 2010; Ponce et al, 2010; Mattocks et al, 2014; McKimman et al, 2013); environmental factors (Davidson et al, 2004; Capezuti et al, 2012); health behaviors (Andersen, 1995; Lasser et al, 2006; Stringhini et al, 2010); acculturation, language, and citizenship (Derose et al, 2009; Kinsler et al, 2009; Zambrana and Carter-Pokras, 2010; Wright et al, 2013); provider proximity (Cordasco et al, 2011; Paquette et al, 2011); available safety-net services (Katz, 2010; Cordasco et al, 2011; Katz and Brigham, 2011; Ku et al, 2011; Chatterjee et al, 2012; Spatz et al, 2012); and the absence of a usual source of care (Phillips et al, 2009; Bodenheimer and Pham, 2010). Even in health care

systems that are considered to provide “equal access,” such as the U.S. Department of Veterans Affairs hospitals, different patient groups use outpatient and inpatient care at markedly different rates, leading to variations in outcomes (Jha et al, 2001; Kizer and Dudley, 2009; Frayne et al, 2013).

In this context, differential access to care has been proposed as an important determinant of racial and ethnic disparities in prostate cancer screening, treatment, morbidity, and mortality (Moul et al, 1995; Optenberg et al, 1995; Klabunde et al, 1998; Stitzenberg et al, 2012; Barocas et al, 2013a). Discrepancies in accessibility and continuity of medical care may explain the lower use and awareness of prostate-specific antigen (PSA) testing among Hispanic men in the United States (McFall, 2006; Spencer et al, 2006; McFall, 2007); it remains unknown whether access or continuity issues mediate the greater dissatisfaction with prostate cancer treatment decisions among Hispanic men (Hoffman et al, 2003; Resnick et al, 2013a). Access to health care reflects not only the potential for entry into the health care system, but also the actual consumption of services. In one public-assistance program for low-income, uninsured men with prostate cancer, special attention to overcoming the financial and nonfinancial barriers has eliminated racial and ethnic disparities in health services use (Miller et al, 2008a). Nonetheless, because men from historically disadvantaged groups often do not access adequate and timely care, they continue to suffer a disproportionate burden (Miller et al, 2009a).

COSTS OF CARE

The cost of medical care may be measured in many ways. Although it is difficult to put a price tag on the toll of human suffering, physicians today are asked to reduce costs, improve quality, and provide services for greater numbers of patients in an increasingly austere environment. This often requires rationing of resources, though it is seldom explicitly labeled as such. In the present era of sweeping change in health care financing and health services delivery, increasing emphasis has been placed on efficiency in the allocation of scarce medical resources. The field of medical economics is well beyond its nascence, and broad public interest has emerged in studying the costs of medical and surgical therapies. As we spend more administrative dollars on cost containment, scrutiny is reaching all potential areas for conservation, including oncology—a province once considered sacred and off limits to cost-cutting efforts.

Health policy decisions today must be based not only on biomedical research but also on sound evaluations of health care costs. The use of oral erectogenic medications, beginning in the late 1990s, provides a perfect illustration of the tension between therapeutic advances and economic forces. The scientific discoveries that led to the advent of sildenafil and similar agents (Rajfer et al, 1992) were rewarded with a Nobel Prize, yet insurers initially fervently

resisted paying for them (McGarvey, 2000; Smith and Roberts, 2000). This led to widespread controversy, generated numerous studies, and even raised questions of constitutional law (Finley, 1999; Julka, 1999; Connolly, 2001; Haff, 2006; Ki and Kim, 2008). As a surgical subspecialty whose practitioners have discovered and use several exciting but expensive new drugs (Kantoff et al, 2010; de Bono et al, 2011; Fizazi et al, 2011; Cabot et al, 2012; Parker et al, 2013), urology is at the forefront of helping patients make rational health care choices and balance competing priorities. Urologists must be especially conscientious and evidence based in advocating for new and expensive therapies, given the human toll (Gore et al, 2009a; Huang et al, 2010; Johansson et al, 2011; Song et al, 2011; Holmberg et al, 2012; Harden et al, 2013) and economic ramifications (Bolenz et al, 2010; Krahn et al, 2010; Andersson et al, 2011; Nguyen et al, 2011; Lowrance et al, 2012b) of overtreatment of indolent prostate cancer (Daskivich et al, 2010a, 2010b, 2011a, 2011c; Chamie et al, 2012a) over the past two decades.

Terms and Methods of Analysis

In its purest form, research on health care costs involves counting the amount of money that is spent on facilities, equipment, supplies, and personnel during the provision of medical care. But many costs are hidden. A more extensive approach would also include the opportunity cost of the time patients spend receiving care. For example, when estimating the cost of an interval cystoscopy after resection of a bladder tumor, a thorough assessment would include not only the cost of overhead, supplies, lidocaine jelly, urine cytology, and professional fees, but also the cost to the patient in lost wages—or to his or her employer in lost productivity—during the time away from work for the procedure, travel, or any complications. This component is not insignificant. Employee absence from work has been estimated to cost U.S. businesses tens of millions of dollars annually (Loeppke et al, 2009; Volpp et al, 2011; Zhang et al, 2011).

Because true costs are difficult to quantify at the individual, institutional, or population level, researchers instead often report data on charges. *Charges* represent the amount that is billed for a service, whereas *costs* reflect what the provider spent to supply that service. Most of the available administrative databases in health care are based on either financial discharge abstracts from hospitals or claims data from large payers, insurance companies, or government agencies such as the Centers for Medicare and Medicaid Services. These data sets primarily include information on charges and payments, but not costs. The major advantage of using charge data is that they are much easier to obtain. The primary disadvantage is that they may not accurately reflect the true underlying costs of individual medical services. For example, a hospital that is losing money on magnetic resonance imaging may make up the deficit by increasing its charges for urine cytology procedures. This practice may help balance the annual budget, but it corrupts the quality of the charge data. An economic analysis using charges for bladder cancer follow-up in such a hospital will err by incorporating the inflated amounts charged for interval urine cytology procedures. Some analysts attempt to circumvent this problem by calculating a ratio of costs to charges for entire facilities, individual medical services, or diagnosis-based categories of care. Charges are frequently used to estimate the amount of money spent on health care, although such calculations are imperfect. To avoid the inherent problems in calculating costs and charges, some researchers instead measure *resource utilization* in terms of duration, frequency, and intensity of services (Washburn et al, 2006; Unroe et al, 2010).

One of the most commonly reported units of comparative analysis is length of stay (LOS). After 1983, when the prospective payment system was instituted to reimburse hospitals a predetermined amount of money on the basis of the diagnosis-related group (DRG) into which each Medicare inpatient is classified (Vladeck, 1984; Hsia et al, 1988; Goldfield, 2010), attention to LOS as an outcome variable in cost analyses greatly increased. In the United States, inpatient LOSs are now believed to have reached their floor, and effort has shifted from this measure. Costs of care may be

measured as intensity or numbers of services provided. For example, rather than calculating the costs or charges for a 3-day hospitalization for radical nephrectomy, analysis may be based on the total number of complete blood counts, chest radiographs, bags of intravenous fluid, doses of antibiotic, and doses of narcotic and antibiotic ordered on any given day of the hospital stay or during the entire stay. By examining duration or frequency of medical services when studying costs, researchers can avoid the biases involved in using financial data. Although the overall costs of diseases such as bladder cancer are high (James and Gore, 2013), opportunities for quality improvement often go hand in hand with cost reduction when pharmacoeconomics are considered (Gore and Gilbert, 2013).

Cost-effectiveness analysis is another popular technique used to evaluate new or established medical therapies. Ideally, preventive care can obviate the need to treat a disease by preventing its onset, and the cost of prevention can be compared with the cost of disease treatment (Maciosek et al, 2010). Alternatively, a cost-effectiveness analysis is performed by developing a probability model of the possible medical outcomes of one intervention compared with another, such as sacral neuromodulation versus medication for storage symptoms (Anger et al, 2014), or with a nonintervention such as watchful waiting for benign prostatic hyperplasia (Saigal and Joyce, 2005; Bellinger et al, 2012; Strope et al, 2012), identifying the expenses associated with each outcome, and comparing the results, typically reported as cost per year of life saved (Lee et al, 2009; Binagwaho et al, 2010; MacKenzie et al, 2010; Wheeler et al, 2010; Ciaranello et al, 2013). Years of life saved, or *life years (LYs)*, are calculated for a population, not for individuals. Ten LYs might represent two patients, each of whom survives for 5 additional years, or 120 patients, each of whom survives for 1 additional month (Baker et al, 2010; Jia and Lubetkin, 2010; Soerjomataram et al, 2012). LYs are usually adjusted to account for different health states that may result from various treatments. These are called *quality-adjusted life years (QALYs)*. For example, when comparing two treatments for localized prostate cancer, if both options are determined to cost \$10,000 per year of life saved, then the two may seem equivalent. However, if one treatment yields years that are compromised by bothersome sexual dysfunction (Le et al, 2010), whereas the other yields years that are free of such problems, then the difference in quality of the years saved must be factored into the equation. Analyses that rely on QALYs are facilitated by the estimation of patient utilities, or preferences, for various health states (Albertsen et al, 1998; Saigal et al, 2001, 2002; Owens and Shekelle, 2013). If patients appraise an impotent year as being worth less than a potent year, then quality adjustments may make the first treatment more expensive per QALY saved. Couples approached 1 year after treatment for prostate cancer were found to be willing to pay approximately \$800 per month for a hypothetical new treatment that cures prostate cancer without side effects (Zeliadt et al, 2010, 2011; Ramsey et al, 2011; Li et al, 2012).

Cost-benefit analysis differs by including not only the costs but also the equivalent monetary value of any benefits garnered during the extra years of life. Often, this refers to wages earned or income accrued during that time. In more sophisticated analyses, future income and expenses related to a particular health state are discounted to present value by incorporating projected interest and inflation rates over time. Reducing cost in the treatment of one disease liberates resources to invest in exciting new projects (Beheshtian and Yel, 2005; Chu et al, 2012). Cost studies may be undertaken as descriptive analyses that chronicle the economic burden of one disease in a group of patients, such as the cost of care for interstitial cystitis in a managed care plan (Clemens et al, 2009; Anger et al, 2011; Beckett et al, 2014). They may examine the financial impact on the general population such as national annual expenditures for urolithiasis (Raman et al, 2010; Lotan and Pearle, 2011; Lotan et al, 2012; Sutherland et al, 2013). They may also track cumulative costs over time, such as for different prostate cancer treatments (Krahn et al, 2010; Snyder et al, 2010; Krahn et al, 2014). Alternatively, they may present economic models comparing different approaches to managing an illness, such as whether it is more

costly to correct cryptorchidism in infants or in older boys (Hsieh et al, 2009), or to manage small renal tumors with laparoscopic or percutaneous cryoablation (Bensalah et al, 2008; Hui et al, 2008; Pandharipande et al, 2008; Panumatrassamee et al, 2013).

Value of Care

The cost of health care should be considered in the context of the outcomes it produces. The “value” of a health care service or intervention is defined as quality divided by cost (Porter, 2010; Weinberger, 2011). Outcomes are more relevant than services rendered, or health care inputs, because significant health inputs without good outcomes do not produce value (Kaplan and Porter, 2011; Berwick and Hackbarth, 2012). Considering cost in the context of value can help policy makers decide which interventions should be amplified and which may be reduced (Orszag and Emanuel, 2010). The ultimate reflection of value is life expectancy divided by cost. The Organisation for Economic Co-operation and Development (www.oecd.org) reports these outcomes. Among 34 participating countries, the United States ranks first in total health expenditures per capita and 26th in life expectancy (Auerbach and Kellermann, 2011; Fuchs, 2013; van Baal et al, 2013). Among 28 participating countries reporting public expenditure on education and 24 describing tertiary education rates, the United States ranks 16th and 15th, respectively (Hudson and Kühner, 2009; Mahon, 2013).

Patterns of Care

Variations in patterns of care are vast, and incompletely understood. The Dartmouth Atlas Project has studied practice patterns most broadly, and for over 20 years has documented glaring variations in distribution and use of medical resources in the United States (Hudson, 1996; Wennberg, 1998). The project uses Medicare data to provide information and analysis about national, regional, and local markets, as well as hospitals and their affiliated physicians. Data from the project demonstrate significant variation among different regions of the country (Weinstein et al, 2006; Wennberg et al, 2008; Wennberg, 2011), especially at the end of life (Morden et al, 2012; Prigerson and Maciejewski, 2012) and often incongruously with patient preferences (Keating et al, 2010; Mitchell, 2010; Patel and Schulman, 2012). That variation in health care spending does not correlate with outcomes suggests that good outcomes can be achieved with lowered cost, and that current spending can be targeted more thoughtfully. In urology, significant hospital-level variation exists in outcomes and readmission after surgery (Gore et al, 2012).

Performance of appropriate and inappropriate procedures often varies concomitantly, as is the case with imaging of men with prostate cancer. Regions with higher rates of indicated imaging also have higher rates of extraneous imaging, and those with lower rates of unnecessary scans have lower rates of appropriate utilization (Lavery et al, 2011; Makarov et al, 2012a, 2012b). National efforts to decrease inappropriate imaging by disseminating utilization data and imaging guidelines to urologists can lead to meaningful decreases in unsupported imaging, but may also reduce appropriate use among high-risk patients (Makarov et al, 2013). Meaningfully improving practice patterns requires fastidious collaboration (Miller et al, 2010, 2011).

Regional variation in bladder cancer cost and outcomes has been noted, with higher-spending regions using more services and interventions, but lower-spending regions demonstrating superior cancer-specific survival (Skolarus et al, 2010). Significant regional variation also exists in the cost of radical prostatectomy (Makarov et al, 2010). Clearly, practice patterns are not always driven by data. For instance, acquisition of a surgical robot increases the number of both robotic and open prostatectomies performed in a hospital referral region (Makarov et al, 2011; Stitzenberg et al, 2012), and increases in surgical treatment of prostate cancer are both geographically and temporally related to acquisition of robotic surgical systems (Makarov et al, 2011; Lowrance et al, 2012a; Stitzenberg

et al, 2012). The increase in the overall number of surgical prostatectomies performed raises concern of overtreatment of men who would otherwise die with, rather than of, their disease (Burgess et al, 2006; Tewari et al, 2006; Steinberg et al, 2008; Andriole et al, 2009; Hu et al, 2009; Hugosson et al, 2010; Andriole et al, 2012; Carter et al, 2012a, 2013b; Huang et al, 2013; Laviana and Hu, 2013; Bolenz et al, 2014). Concerning patterns abound beyond cancer care. Opening of ambulatory surgery centers is associated with increased use of discretionary surgery (Strope et al, 2009; Hollingsworth et al, 2010, 2011; Schroek et al, 2012), and introduction of physician ownership of lithotripter units influences treatment selection (Tan et al, 2011).

Conversely, some evidence-based advances have diffused much more slowly. Adoption of laparoscopic approaches to radical nephrectomy is variable, as is quality of kidney cancer care (Harper et al, 2012). Diffusion of evidence-based technologies and practices is limited by physician preferences, as is the case with partial or laparoscopic nephrectomy for small renal masses (Miller et al, 2006; Morris et al, 2007; Miller et al, 2008b) or continent reconstruction after cystectomy (Gore et al, 2006). Patient age and physician variables do affect practice patterns (Quinn et al, 2009; Cooperberg et al, 2010; Dulabon et al, 2010; Bleich et al, 2011; Klabunde et al, 2013).

The National Institute of Diabetes and Digestive and Kidney Diseases funds the Urologic Diseases in America project (www.udaonline.net), which seeks to define the burden of urologic disease on the American public by quantifying trends in resource usage, practice patterns, costs, outcomes, and epidemiology across the spectrum of urologic conditions (Litwin et al, 2005a, 2005b; Miller et al, 2009b). Documenting these trends has broad implications for quality of health care, access to care, and the equitable allocation of scarce resources, in terms of both medical services and research budgets. Among the most financially burdensome urologic conditions are urolithiasis (Scales et al, 2011), urinary tract infection (Griebing, 2005a, 2005b; Carter et al, 2012b), urinary incontinence (Anger et al, 2006a, 2006b, 2006c; Rogo-Gupta et al, 2013), and benign prostatic hyperplasia (Nickel, 2006; Roehrborn et al, 2011b; Stewart et al, 2012). Urologic diseases exert a substantial impact on resource usage within the U.S. Veterans Affairs health system (Anger et al, 2008).

Analyses from the Urologic Diseases in America project have revealed not only disturbing trends and variations in care, but also avenues for potential improvements for both benign and malignant disease. Surgical quality among Medicare beneficiaries undergoing outpatient urologic surgery varies by location of care delivery (Hollingsworth et al, 2012a). The prevalence of kidney stones has increased sharply, particularly in black, non-Hispanic and Hispanic individuals, and now affects 1 in 11 people in the United States (Scales et al, 2012). Once an individual has been diagnosed with a kidney stone, treatment varies significantly, often driven by nonclinical factors associated with provider and/or patient preferences or experience (Scales et al, 2011). In bladder cancer, delays before radical cystectomy can increase mortality (Gore et al, 2009b), and use of radical cystectomy varies by clinical and sociodemographic factors (Gore et al, 2010b). Adherence to guideline-recommended bladder cancer care is poor (Chamie and Litwin, 2011; Chamie et al, 2011; Chamie et al, 2012b). One exciting positive avenue for expansion is smoking cessation: smokers newly diagnosed with bladder cancer are five times as likely as the general population to quit smoking, especially if counseled appropriately by their urologist (Bassett et al, 2012). For men with prostate cancer, patterns of care after failure of primary prostate cancer treatment depended on use of standardized clinical algorithms, initial therapy, and geographic region (Krupski et al, 2006). Patients with kidney cancer who are treated with partial rather than radical nephrectomy have fewer adverse renal outcomes, including less frequent receipt of dialysis services, dialysis access surgery, or renal transplantation (Miller et al, 2008c). These findings are consistent with a subsequent population-based study using instrumental variable analysis to assess outcomes after partial versus radical nephrectomy, which showed that for individuals with early-stage kidney

cancer, treatment with partial nephrectomy was associated with improved survival (Tan et al, 2012).

Case Mix

In studying patterns of care or medical costs, it is critical to adjust for case mix. *Case mix* refers to the severity of illness and degree of comorbidity in a group of patients (Iezzoni, 1989; Covinsky et al, 1997b; Birkmeyer et al, 2012; Maas et al, 2013). These characteristics may influence treatment outcomes. For example, because they typically have a greater burden of comorbidity, older patients are more likely to experience complications after surgery. This comorbidity must be accounted for in evaluations of clinical outcomes (Hong et al, 2010; Zelefsky et al, 2010; Epstein et al, 2011). Kidneys from donors older than 50 years may provide fewer years of service to their recipient (Ng et al, 2012). If these facts are not considered when comparing surgical complication rates across hospitals, evaluators may erroneously conclude that a hospital with an older patient population is providing poorer care. To use outcomes to measure quality of care, we need to adjust for these other factors including baseline patient characteristics and intervening treatments. This adjustment (referred to as *case-mix adjustment* or *risk adjustment*) can be extremely complex, and the selection of factors must be carried out carefully so that outcomes can be interpreted accurately. For a variety of reasons, sicker patients cost more, and it is important to control for this difference in comparative analyses. In examining the factors that lead to higher hospital charges for more ill patients, two forces must be considered: duration and intensity of care. Duration is usually quantified as inpatient LOS, whereas intensity of care may be assessed as numbers of services or charges per day. Patients with greater comorbidity may remain hospitalized longer even if they do not receive more intense care during their stays. Duration and not intensity appears to be the primary force driving up hospital charges for sicker urology patients (Litwin et al, 1993). Various comorbidity measures (Kaplan and Feinstein, 1974; Charlson et al, 1987; Stier et al, 1999; Crabtree et al, 2000; Di Gangi Herms et al, 2003; Daskivich et al, 2011b, 2011c, 2013a) have been used by researchers to adjust for case mix and predict mortality from competing causes in clinical studies.

The impact of case mix on urologic disease outcomes has been studied most broadly in men treated for prostate cancer. Comorbidity is more important than age in predicting perioperative mortality after radical prostatectomy (Alibhai et al, 2004, 2005; Chamie et al, 2012a; Daskivich et al, 2013b). Among men with high comorbidity, low- and intermediate-risk prostate cancer is overtreated (Daskivich et al, 2010a, 2011a, 2011b, 2011c, 2013a; Chamie et al, 2012a), and often with advanced treatment technologies that have not been shown to be superior to prior standards (Jacobs et al, 2013). Conversely, men with high-risk prostate cancer are undertreated across all levels of comorbidity (Chamie et al, 2012a; Daskivich et al, 2011a, 2013a, 2013b). A revised index that reweighs Charlson comorbidities can more accurately identify men at highest risk for non-prostate cancer mortality, and aid in medical decision making (Daskivich et al, 2011b, 2011c, 2013a).

Comorbidities such as obesity also affect the incidence and severity of benign urologic conditions, including urinary incontinence (Richter et al, 2010), chronic prostatitis and chronic pelvic pain syndrome (Anothaisintawee et al, 2011), benign prostatic hyperplasia and lower urinary tract symptoms (Schenk et al, 2010; Parsons et al, 2013), and erectile dysfunction (Chitale et al, 2009; Tsai and Sarwer, 2009). Weight loss meaningfully reduces incontinence in overweight and obese women (Subak et al, 2009; Smith et al, 2010), and lengthens life expectancy as well (Keating et al, 2009; Stewart et al, 2009; Majer et al, 2011).

Cost Savings in Urology

As the cost of health care expands (Sutherland et al, 2009; Kellermann and Weinick, 2012) and crowds out other societal priorities (Auerbach and Kellermann, 2011), urologists have continued their central role in the ongoing struggle to balance the

sometimes-competing priorities of minimizing costs and maximizing quality (Botteman et al, 2003; Lotan, 2009; Lotan and Pearle, 2011; Staskin et al, 2012). For common procedures, such as transurethral resection of the prostate, urologists standardized care and cut costs long before it was mandated by the government (Sage et al, 1988). They made similar improvements for radical prostatectomy (Kramolowsky et al, 1995a, 1995b; Konety et al, 1996) and nephrectomy (Wilson et al, 1995; Uzzo et al, 1999). Unfortunately, such initiatives were insufficiently broad and sustained (in urology and beyond) to achieve high-quality care at sustainable cost throughout health systems, and the government intervened to buttress efforts to minimize cost and maximize quality. Medicare's pay-for-performance program differentially reimburses hospitals, medical groups, and clinicians based on adherence to quality metrics and elimination of medical errors (Rosenthal et al, 2004; Kindig, 2006). The need to realign incentives was reinforced by the Institute of Medicine's report, *Rewarding Provider Performance: Aligning Incentives in Medicare*, which stated, "The existing systems do not reflect the relative value of health care services in important aspects of quality, such as clinical quality, patient-centeredness, and efficiency" (Fisher, 2006). It recommended pay-for-performance as an immediate opportunity to better align incentives for improved performance. Methods of standardizing care and improving quality include clinical pathways, which have maximized value for hematuria (Vasdev et al, 2012), incontinence (Romeyke and Stummer, 2012; Rotter et al, 2012), and prostatitis (Shoskes, 2008), among others.

As an extension of this concept, under the Patient Protection and Affordable Care Act of 2010 (which was almost fully implemented in 2014), Medicare fee-for-service is being restructured into "bundled payments." A bundled payment is a single payment for an episode of care, such as a radical prostatectomy, rather than reimbursement to individual entities or providers based on services rendered. An interesting historical footnote is that the first self-imposed bundled payment was taken on by the father of American urology, Hugh Hampton Young. In his autobiography, Dr. Young described a patient on whom he agreed to perform a prostatectomy in the 1920s for a fixed fee of \$500 with a promise of only 3 weeks in the hospital. Because the patient developed complications and remained hospitalized for much longer than planned, Young had to spend his entire professional fee plus an additional \$350 to pay off the hospital bill (Young and Didusch, 1940).

The Affordable Care Act also includes several incentive programs that should affect individuals with urologic diseases. For instance, the act supports participatory wellness programs, which would reimburse for the cost of membership in a fitness center, potentially mitigating the noxious effect of obesity on prostate cancer (Freedland et al, 2008a, 2008b; Jayachandran et al, 2008, 2009; De Nunzio et al, 2012; Gollapudi et al, 2012; Keto et al, 2012; Byrd et al, 2013; Wu et al, 2013). Likewise, it supports employees attending no-cost health education seminars, including smoking cessation classes, which has significant consequences for individuals with bladder cancer (Bassett et al, 2012).

QUALITY OF CARE

Quality of care research evaluates "the degree to which health services for individuals and populations increase the likelihood of desired health outcomes and are consistent with current professional knowledge" (Brook and Lohr, 1981, 1985; Lohr, 1988; Lohr et al, 1988; Donabedian et al, 1989). The Institute of Medicine's landmark report *Crossing the Quality Chasm* outlined six principles that define high-quality health care: care that is safe, effective, efficient, patient-centered, timely, and equitable (Institute of Medicine, 2001). More recently, greater emphasis has been placed on efficiency, or value-based care, with value defined as patient-centered health outcomes divided by cost (Porter, 2010; Swensen et al, 2010; James and Savitz, 2011).

To reach a desired patient-centered health outcome, provided services must satisfy both content quality and delivery quality.

Content quality involves the technical component of health care and includes quality processes and metrics (James, 1989; Washington and Lipstein, 2011). It is defined and evaluated by health care providers. Delivery quality addresses interpersonal relationships on which delivery of health services are based, and is evaluated by patients and caregivers. Continuous quality improvement is the guiding principle for establishing a high-quality health care delivery system, and relies on an electronic health record system as well as on quality improvement oversight (Pham et al, 2007; Gabow et al, 2012; Cosgrove et al, 2013). An electronic health record system can improve quality on the front end with electronic order entry, built-in order sets, and standardized clinical care pathways, and on the back end with facile data abstraction and reports built around broad sets of quality outcomes (Gabow and Mehler, 2011; Cosgrove et al, 2012). Electronic systems are easily modifiable for changing metrics over time, and cloud-based systems allow sharing of information between inpatient and outpatient facilities, as well as with other institutions (Schweitzer, 2012). Compared with other industries, information technology has been less aggressively adopted in health care (Menachemi et al, 2006; Simon et al, 2007). As of 2008, fewer than 20% of physicians used an electronic health record (DesRoches et al, 2008; Jha et al, 2009). The Health Information Technology for Economic and Clinical Health Act of 2009, part of the government's stimulus package, provided funding for adoption and meaningful use of electronic health records, to achieve improvements in care (Blumenthal, 2009; Jha et al, 2009). Hospitals and physicians not using electronic health records by 2015 are subject to financial penalties under Medicare. Quality improvement oversight is typically undertaken by a quality improvement department, and involves data collection and monitoring systems, confidential reporting, and dashboards (Gabow et al, 2012). Such quality improvement projects have been piloted in urology but have not yet been implemented broadly (Gambone and Broder, 2007; Lee et al, 2011).

Descriptive quality measures abound, but for quality metrics to affect outcomes, they must be based on solid evidence, be feasible, and have resources devoted to tracking and improvement. In 2005, the U.S. Congress passed the Patient Safety and Quality Improvement Act, which helped reinforce ongoing quality improvement initiatives and also launched several new initiatives to collect and disseminate performance information about medical care (Patient Safety and Quality Improvement Act, 2005). For example, the ECRI Institute (www.ecri.org) collects and analyzes data about adverse events as well as near misses. The National Committee for Quality Assurance (www.ncqa.org) provides information to health care purchasers about the comparative performance of health plans in the United States. The Joint Commission (TJC, www.jointcommission.org) applies outcomes-based quality measures to accredited hospitals, and TJC accreditation is mandatory for participation in Medicare. Hundreds of performance indicators have been collected in its National Library of Healthcare Indicators, and a root cause analysis system was developed to understand the causes of sentinel events. The National Quality Forum (www.qualityforum.org/home.aspx) has focused on patient safety and endorsed six sets of "never events." The Leapfrog Group (www.leapfroggroup.org) includes almost 200 large private and public health care purchasers that attempt to leverage their purchasing power to influence quality and affordability. The Leapfrog Safe Practices Score assesses computer physician order entry, evidence-based hospital referral, and appropriate intensive care unit staffing. Leapfrog volume thresholds suggest that individuals undergoing radical prostatectomy at high-volume institutions have shorter LOSs and receive fewer blood transfusions compared with those treated at low-volume institutions (Penson, 2013). The Institute for Healthcare Improvement (www.ihl.org) is a nonprofit organization seeking to optimize health care performance by improving quality and patient satisfaction, improving the health of populations, and reducing the per capita cost of health care. The National Patient Safety Foundation (www.npsf.org) was formed in partnership between the American Medical Association and private industry to provide research support, education, and leadership training in

patient safety. It holds an annual Patient Safety Congress and publishes the *Journal of Patient Safety*. The Institute for Safe Medication Practices (www.ismp.org) aims to reduce medication error and operates an anonymous practitioner reporting program to understand the causes of medication errors and to eliminate them.

One of the most widely used performance measures, maintained by the National Committee for Quality Assurance, is the Healthcare Effectiveness Data and Information Set (HEDIS, www.ncqa.org/hedisqualitymeasurement). HEDIS's 75 measures are divided into eight domains: effectiveness, access/availability, experience, health plan stability, utilization and relative resource use, cost, informed health care choices, and health plan descriptive information. Consumers can use these data to compare the performance of health plans; the Centers for Medicare and Medicaid Services uses HEDIS to determine reimbursement for enrollees in Medicare Advantage. The broadest set of measures specific to surgery is the American College of Surgeon's National Surgical Quality Improvement Program (NSQIP) (Birkmeyer et al, 2008). The measures quantify risk-adjusted 30-day surgical outcomes, including mortality and morbidity in 21 categories. Collection and reporting of NSQIP measures have been shown to improve outcomes (Hall et al, 2009). Another often-used set of indicators is the Patient Safety Indicators (www.qualityindicators.ahrq.gov) published by the U.S. Department of Health and Human Services' Agency for Healthcare Research and Quality (AHRQ). The indicators focus on hospital and postoperative complications. On the basis of extensive reviews of available evidence, AHRQ developed four categories of quality indicators (prevention, patient safety, inpatient, and pediatric), which are now being used to modulate hospital and physician reimbursement.

Several consumer groups also publish health care performance metrics. The Foundation for Accountability (www.facct.org), a consumer organization, creates tools that help people understand and use quality information, develops consumer-focused quality measures, supports efforts to gather and provide quality information, and encourages health policy to empower and inform consumers. Consumer Reports uses Medicare billing data to rate surgical performance (www.consumerreportshealth.org); such approaches have been criticized for lacking critical clinical data (Conaboy, 2013). Families USA (www.familiesusa.org) is a nonprofit organization that produces health policy reports outlining problems from a consumer perspective and describing steps to solve them.

Quality Conceptual Framework

The conceptual framework for the measurement of quality of care in medicine was established almost 50 years ago by Donabedian (Donabedian, 1966). In this model, quality-of-care measures are categorized into three domains—structure, process, and outcome.

Structure of Care

Structure encompasses the fixed aspect of health care delivery and includes the space, equipment, human resources, and provider experience necessary to provide care. Examples include clinician characteristics (e.g., percentage of physicians who have board certification, average years of experience, distribution of specialties); organizational characteristics (e.g., staffing patterns, reimbursement method); patient characteristics (e.g., insurance type, illness profile); and community characteristics (e.g., per capita hospital beds, transportation system, environmental risks). Structural measures specific to prostate cancer quality could include the presence of a multidisciplinary cancer center or psychological support services (Spencer et al, 2003).

Although certain structural characteristics may be necessary to provide good care, they are usually insufficient to ensure high-quality care. Therefore the best structural measures are those that can be shown to have a positive influence on the process of care and on patient outcomes (Brook and McGlynn, 1996). One structural measure that is positively associated with outcomes is the number of patients treated by a particular physician or institution, especially for major procedures such as radical cystectomy

(Hollenbeck et al, 2007a, 2007b; Porter et al, 2011; Morgan et al, 2012) or radical prostatectomy (Siu et al, 2008; Trinh et al, 2013). Surgeon volume is also associated with structural covariates such as lymph node count at the time of robotic cystectomy (Marshall et al, 2013). Hospitals with higher lymph node counts have been shown to have higher survival rates after radical cystectomy (Hollenbeck et al, 2008). Patients with renal trauma are more likely to be offered conservative management and have a lower chance of requiring multiple procedures if they are treated at a level 1 trauma center (Hotaling et al, 2012).

Process of Care

Process of care is the set of activities that goes on between patients and practitioners and is often divided into interpersonal process and technical process. Examples include antibiotic prophylaxis and discussion of treatment options (Wolf et al, 2008). Process measures are often considered to be the best measure of quality (Brook and McGlynn, 1996; Brook et al, 2000), and the most fertile area for improvement in value (Schneider et al, 2004; Malin et al, 2006). *Interpersonal process* refers to how the clinician relates to the patient and includes issues such as whether the clinician supplies sufficient information in a clear enough manner for the patient to make an informed treatment choice. Patient survey data are generally used to assess quality of interpersonal process. *Technical process* refers to whether medically appropriate decisions are made when diagnosing and treating the patient and whether care is provided in an effective and skillful manner—for instance, selecting the correct operative repair for female urethral stricture disease (Ackerman et al, 2010). One way to evaluate the appropriateness of medical treatment is to determine if the care provided is consistent with current medical knowledge and adheres to the professional standard. This assessment can be done by developing *quality indicators*, such as those delineated earlier, that describe a process of care that should occur for a particular type of patient in a specific clinical circumstance. To be valid, these quality indicators should be based on the evidence in the medical literature and on current professional standards of care. Determining the latter often requires an expert panel to achieve consensus. The performance of physicians and health plans is then assessed by calculating rates of adherence to the indicators for a sample of patients. Using quality indicators to evaluate appropriateness of care is relatively straightforward. However, assessing the effectiveness or skill of technical process of care is much more difficult. Indeed, direct observation may be necessary to assess the quality of technical process of care. Alternatively, it may be necessary to rely on measuring outcomes to evaluate whether care was provided in a skillful manner. For example, measurement of surgical blood loss or number of specimens with positive margins, both surgical outcomes, may be indicators of the quality of surgical technical process. Conversely, operative time may represent the surgeon's manual dexterity or the technical complexity of a case. Hence celerity is not generally considered an accurate indicator of operative quality.

Outcomes of Care

Outcomes include changes in patients' current and future health status including health-related quality of life (HRQOL) and satisfaction. Cancer researchers generally use survival or progression-free survival as the main outcome measure in clinical studies. Sometimes proxy measures (also called *surrogate end points* or *intermediate outcomes*) that do not measure the outcome directly but are thought to be correlated with it are used. When a proxy measure is used as a quality indicator, there must be evidence that the proxy measure is truly a substitute for the outcome of interest. For example, the presence of unfavorable PSA kinetics after treatment for localized prostate cancer appears to be associated with cause-specific mortality (Freedland et al, 2005; Roach et al, 2006; Stephenson et al, 2009; Eggener et al, 2011), so this may be a reasonable proxy outcome. Although the ultimate outcome may be mortality, many conditions in urology such as prostate cancer

take an indolent course, making mortality impractical (and often irrelevant). In such conditions, more proximal outcomes such as LOS, complications, and the need for salvage therapy provide a useful proxy (Bastide et al, 2010; Eggener et al, 2011). For proxy measures to be useful as quality measures, intervention should affect both the measure and the underlying disease (Guyatt et al, 1993; Girling et al, 2012).

The most important patient-reported outcome is HRQOL, a multi-dimensional construct that includes somatic symptoms, functional ability, emotional well-being, social functioning, and body image, as well as overall well-being (Guyatt et al, 1993; Wilson and Cleary, 1995). Quality-of-life assessment, typically by patient survey, provides a comprehensive evaluation of how the illness and its treatment affect patients.

Quality Metrics Applied to Urology

General quality metrics applied to urology have shown that patients undergoing cystectomy, nephrectomy, and prostatectomy are at significant risk of developing deep venous thromboses or pulmonary emboli (Gore et al, 2012). Readmission and mortality are highest after cystectomy, with readmission rates of over 35% and mortality over 6% after 90 days. Measurable variation in surgical quality exists by location of surgery for a range of outpatient urologic procedures (Hollingsworth et al, 2012a).

Urology-specific quality indicators and covariates have been developed, validated, and applied for localized prostate cancer (Spencer et al, 2003; Miller et al, 2007; Spencer et al, 2008; Ritchey et al, 2012). The 48 quality-of-care indicators include 5 structure, 23 process, and 20 outcome variables, plus 15 covariates (such as patient age). Quality metrics specific to bladder cancer have been proposed but have yet to be developed and validated (Montgomery et al, 2013). Candidate structure indicators include use of multidisciplinary teams, operating room facilities, and surgical volume (Cooperberg et al, 2009); process measures include adequate staging, complication rates, chemotherapy at transurethral resection, neoadjuvant or adjuvant chemotherapy use, time to cystectomy, adequate lymphadenectomy, and discussion of continent diversion if appropriate (Cooperberg et al, 2009; Gore et al, 2009b; Chamie et al, 2012b); and outcome measures include morbidity, mortality (overall and disease specific), and HRQOL, which would be best evaluated with bladder cancer-specific instruments (Gore et al, 2012).

Quality metrics for kidney cancer also have not been formalized, but use of partial versus radical nephrectomy in individuals with early-stage cancer may be a good candidate. All-cause and kidney cancer-specific mortality are lower when partial nephrectomy is employed when feasible (Tan et al, 2012). Clinical pathways for patients undergoing radical nephrectomy hold promise in shortening hospital stay and reducing cost (Chang et al, 2000). Disease-specific metrics have been developed and validated for urinary incontinence (Anger et al, 2013a) and prolapse (Anger et al, 2013b), but they still need to be tested for feasibility.

Advanced cancer and benign diseases have been left behind in urologic quality monitoring. Disease-specific metrics are needed for nephrolithiasis (Donnelly et al, 2011), benign prostatic hyperplasia (McVary et al, 2011), stricture disease (Jackson et al, 2012), and erectile dysfunction (Avasthi et al, 2011), among others (Clavijo et al, 2010; Kaplan and Hu, 2013). For end-of-life care, the National Quality Forum has endorsed the need to improve quality (Lorenz et al, 2006, 2007; Seow et al, 2009a, 2009b). Although knowledge about interventions to improve supportive care is abundant (McNiff et al, 2008; Wright et al, 2008; Zhang et al, 2009; Engelberg et al, 2010; Temel et al, 2010; Walling et al, 2010; Curtis et al, 2011; Malin et al, 2011; Meyer, 2011; Teno et al, 2013), tools to evaluate whether patients receive effective supportive care are lacking, limiting provider ability to improve over time. The Cancer Quality-ASSIST Project used the VA Health Services Research and Development appropriateness method to identify quality indicators in six categories: pain, depression, dyspnea, nausea and vomiting, fatigue and anorexia, and other treatment-related toxicities (Lorenz et al, 2009;

Dy et al, 2010). These metrics are specific neither to urology nor to life's final days. Moving forward, quality-of-care indicators need to be defined, validated, and used for individuals with kidney cancer, bladder cancer, locally invasive and metastatic prostate cancer, benign disease, and advanced urologic malignancies.

Quality Improvement Frameworks

Several health systems have committed to institution-wide quality improvement frameworks. The Lean model of continuous quality improvement was used by most of these systems, although each adapted Lean principles to suit the specific needs of its organization (Mazzocato et al, 2010; Blackmore et al, 2013). The method was originally used by the Toyota Production System, which sought to eliminate waste in production and maximize value for the customer. The process empowers all stakeholders in an institution to identify waste (defined as anything that does not add value or serve the patient's needs), suggest improvement, measure results, and pursue continuous improvement. Several health care systems, including Virginia Mason, ThedaCare, Intermountain, and Denver Health, have employed Toyota's Lean methodology to improve value (Mazzocato et al, 2010; Gabow and Mehler, 2011; James and Savitz, 2011; Gabow et al, 2012; Blackmore et al, 2013; Cosgrove et al, 2013). Nursing always plays a critical role in quality improvement initiatives. Return on investment is high, with savings of up to \$160 million over a 5-year period (Cosgrove et al, 2013; Gabow and Mehler, 2011).

Quality improvement frameworks have been created specifically for and implemented in urology. The Urological Surgery Quality Collaborative and the Michigan Urologic Surgery Improvement Collaborative connect urologists from different practices and feed back data for individual and group quality improvement (Miller et al, 2010, 2011; Burks et al, 2012; Barocas et al, 2013b). The collaboration has succeeded in improving the appropriate use of bone scan and computed tomography imaging for men with localized prostate cancer by lowering overuse when imaging is not indicated and increasing use when it is needed (Miller et al, 2010). It has also improved use of intravesical chemotherapy after transurethral resection of bladder tumors (Barocas et al, 2013b) and reduced variations in practice patterns and improved adherence to recommended staging practices (Miller et al, 2010). Another paradigm shift led by urology involves graphic representation of quality-of-life outcomes, to make measures more actionable for individuals with urologic malignancies. This user-centered design improves patient comprehension and enhances the clinical experiences of men with prostate cancer (Izard et al, 2012).

Integrated patient-centered medical homes also hold promise in improving value and quality in urology (Fisher, 2008). Such a model, with each patient empanelled to a unique primary care physician overseeing his or her medical care, improves care integration and quality (Coleman et al, 2010; Marx et al, 2011; Driscoll et al, 2013; Sarfaty et al, 2013). Nearly three quarters of urology practices currently meet the National Committee for Quality Assurance's standard for a medical home (Sakshaug et al, 2013), and primary care providers devote significant time to care for survivors of urologic malignancies. In contrast, only 54% of all physician practices have sufficient medical home infrastructure (Hollingsworth et al, 2012b). However, in safety-net and other systems, specialty resources are scarce, and successful strategies have placed the face-to-face onus on primary care providers, buttressed by specialist support (Chen et al, 2010; Neuhausen et al, 2012; Chen et al, 2013). Whether the optimal medical neighborhood will be built by employing urologists at the center of a medical home (Sakshaug et al, 2013) or in a supportive role (Chen et al, 2010, 2013) remains an open question (Hollingsworth et al, 2012b; Sakshaug et al, 2013).

Challenges to Using Outcomes to Evaluate Quality of Care

Adverse outcomes may be uncommon events, so large samples of patients may be necessary when using outcome measures to detect

differences in quality among health systems or hospitals. For example, to detect a 2% difference in the rate of postoperative wound infections between two hospitals (e.g., 5% for 1 and 7% for the other), each hospital would need to have at least 1900 patients who had undergone the surgery. In addition, a single outcome may be affected by many different factors, making it difficult to establish accountability. When comparing differences in surgical outcomes across hospitals, one does not know if the differences in outcomes are related to the skill of the surgeon, the competence of the surgical team, the postoperative care, the case mix, or some unmeasured factor. And the more time that elapses between the intervention and the outcome, the more difficult this problem becomes. For example, in comparing 10-year outcomes in women treated for incontinence at different facilities, what is more important, the quality of the initial treatment or the quality of care for recurrent symptoms?

Using patient satisfaction as an outcome is also fraught with limitations (Neuhausen and Katz, 2012). Although higher patient satisfaction is associated with increased overall health care expenditures and drug prescription (Fenton et al, 2012), a relationship between patient experience and quality of care does not necessarily exist (Chang et al, 2006; Rao et al, 2006). In one study, high satisfaction correlated with increased mortality (Fenton et al, 2012). Factors other than quality appear to affect patient satisfaction, and incentives based on satisfaction scores may unintentionally lead to worse outcomes and higher cost. Medicare's Value-Based Purchasing program will penalize hospitals that score poorly on patient satisfaction surveys (Chatterjee et al, 2012; Shoemaker, 2012; VanLare and Conway, 2012; Weston et al, 2013).

Levels of Evidence

Ranking systems to classify levels of evidence were first described by the Canadian Task Force on the Periodic Health Examination in the late 1970s (Delbanco and Taylor, 1980). These have since been adapted to reflect the strength of a study or clinical trial. Evidence levels range from I to IV, as follows:

- Level Ia: Meta-analysis of randomized controlled trials
- Level Ib: At least one randomized controlled trial
- Level IIa: At least one well designed, controlled trial, not randomized
- Level IIb: At least one well designed experimental trial
- Level III: Case, correlation, or comparative study
- Level IV: Expert opinion

Level I evidence is considered most strongly when policy recommendations are being constructed (Moyer, 2012).

HEALTH-RELATED QUALITY OF LIFE

Health-related quality of life encompasses a wide range of human experience including the daily necessities of life such as food and shelter, intrapersonal and interpersonal responses to illness, and activities associated with professional fulfillment and personal happiness (Barofsky, 2012). Contemporary interpretations of HRQOL are based on the World Health Organization's long-standing definition of health as a "state of complete physical, mental, and social well-being and not merely the absence of disease" (Sharp, 1947; World Health Organization, 1948). HRQOL involves patients' own perceptions of their health and ability to function in life. In light of evidence that survival and clinical outcomes may be similar across treatments for many conditions, quality-of-life considerations may be the critical factor in medical decision making in some instances. Data are collected with HRQOL surveys, called *instruments*. Instruments typically contain questions, or items, that are organized into scales. Each scale measures a different aspect, or domain, of HRQOL. Instruments are best when they are self-administered by the patient, but if interviewer assistance is required, it must be from a neutral third party in a standardized fashion (Chang et al, 2011).

Health-Related Quality-of-Life Instruments

HRQOL instruments may be general or disease specific. General HRQOL domains address the components of overall well-being, whereas disease-specific domains focus on the impact of particular organic dysfunctions that may affect HRQOL. Numerous HRQOL instruments have been validated for use in urologic and other conditions. In urology, HRQOL research has been broad, but much has focused on individuals with prostate cancer (Litwin et al, 1995; Litwin et al, 1998; Huang et al, 2010; Mehnert et al, 2010; Ramsey et al, 2010; Szymanski et al, 2010; Resnick and Penson, 2012; Resnick et al, 2013a, 2013b; Resnick and Penson, 2013), urinary incontinence (Richter et al, 2010; Smith et al, 2010; Chong et al,

2011; Coyne et al, 2012; Liebergall-Wischnitzer et al, 2012), benign prostatic hyperplasia (McConnell et al, 2003; Coyne et al, 2009; Montorsi et al, 2010; Roehrborn et al, 2011a; Chokkalingam et al, 2012; Roehrborn et al, 2013), end-stage renal disease (Abdel-Kader et al, 2009; Goldstein et al, 2009; Griva et al, 2009), and bladder cancer (Nagele et al, 2006; Gilbert et al, 2010; Hedgepeth et al, 2010; Large et al, 2010; Nagele et al, 2012). A comprehensive resource for validated HRQOL instruments is available at www.proqolid.org. The National Cancer Institute has been particularly active in establishing interest in outcomes measurement for patients with malignant disease (www.outcomes.cancer.gov). Table 4-1 presents many of the validated HRQOL instruments available for the assessment of patients with urologic conditions. For each

TABLE 4-1 Characteristics of Health-Related Quality-of-Life (HRQOL) Instruments in Urologic Diseases

INSTRUMENT NAME	ITEMS	TIME RECALL, WEEKS	READING GRADE LEVEL OF ITEMS, MEDIAN (RANGE)	REFERENCE
GENERAL HRQOL				
Medical Outcomes Study 36-Item Health Survey (SF-36)	36	4	5.9 (2.2-12.0)	Ware and Sherbourne, 1992
Medical Outcomes Study 12-Item Health Survey (SF-12)	12	4	5.2 (2.2-12.0)	Ware et al, 1996
Quality of Well-Being Scale (QWB)	24	1	6.3 (0.9-12.0)	Kaplan et al, 1976
Sickness Impact Profile (SIP)	136	1 and 7	7.4 (0.5-12.0)	Bergner et al, 1981
Nottingham Health Profile (NHP)	38	At present	4.5 (2.1-12.0)	Hunt et al, 1985
Profile of Mood States (POMS)	65	1	7.2 (0.6-12.0)	Norcross et al, 1984
Mental Health Inventory (MHI)	38	4	5.8 (0.6-12.0)	Berwick et al, 1991
McGill-Melzack Pain Questionnaire	20	At present	N/A	Melzack, 1975
GENERAL HRQOL IN CANCER				
Functional Assessment of Cancer Therapy–General (FACT-G)	28	1	3.4 (1.1-12.0)	Cella et al, 1993

instrument, the table includes the number of items, recall time, and Flesch-Kinkaid reading grade level (Flesch, 1948; Kincaid et al, 1975).

General Health-Related Quality-of-Life Instruments

General quality-of-life instruments have been extensively studied and validated in many types of patients, sick and well. Examples include the RAND Medical Outcomes Study 36-Item Health Survey, also known as the SF-36 (Ware and Sherbourne, 1992; Hays et al, 1993; McHorney et al, 1994), the Quality of Well-Being scale (Kaplan et al, 1979; Bush et al, 1982; Anderson et al, 1989), the Sickness Impact Profile (Bergner et al, 1976a, 1976b; Carter et al, 1976; Martin et al, 1976; Pollard et al, 1976; Gilson et al, 1980; Bergner et al, 1981), and the Nottingham Health Profile (Martini and McDowell, 1976; Hunt et al, 1981). Each assesses various components of HRQOL including physical and emotional functioning, social functioning, and symptoms. Each has been thoroughly validated and tested for reliability, validity, and responsiveness. Another approach to quantifying general HRQOL is to blend a self-assessment of physical, emotional, and social functioning and well-being with a self-report of preferences, or utilities, for those health states. Developed by the Euroqol Group, a measurement collaborative, the EQ-5D is such an instrument (Brooks et al, 1991; Johnson et al, 1998; Johnson and Coons, 1998; Johnson et al, 2005; Shaw et al, 2005; Nan et al, 2007; Pickard et al, 2012).

Benign Disease–Targeted Health-Related Quality-of-Life Instruments

The best-known outcomes instrument in urology is no doubt the American Urological Association Symptom Index (AUASI) (Barry et al, 1992a, 1992b; O’Leary et al, 1992; Barry et al, 1995a). Its simplicity belies its elegance and utility. It includes seven items, each self-rated on a scale of 0 to 5, yielding a summary score that ranges from 0 to 35. Symptom scores are considered mild (0 to 7), moderate (8 to 19), or severe (20 to 35). It has been used to longitudinally assess symptoms in men treated for prostate cancer (Gore et al, 2010a). With the addition of a separate quality-of-life item, the worldwide urology community embraced the AUASI as the International Prostate Symptom Score (IPSS) (Plante et al, 1996; Badia et al, 1997, 1998; Garcia-Losa et al, 2001).

Modeled after the AUASI, and in an attempt to standardize assessment of urinary incontinence and allow cross-cultural comparisons, the Scientific Committee of the International Consultation on Incontinence (ICIQ) supported the development and validation of a universally applicable questionnaire for research as well as clinical practice (Abrams et al, 2010). The ICIQ–Urinary Incontinence Short Form has now been translated into 30 languages (Abrams et al, 2006; Hashim et al, 2006; Klovning et al, 2009; Timmermans et al, 2013). Other high-quality questionnaires were included under the ICIQ umbrella and are available at www.iciq.net. Table 4-2 details some of the validated and published ICIQ modules endorsed by the Fourth International Consultation on Incontinence (Abrams et al, 2010).

Cancer-Specific Health-Related Quality-of-Life Instruments

Because of the well-documented impact of malignancies and their treatment on HRQOL, cancer-specific domains have also been investigated extensively. Numerous instruments have been developed and tested that measure the special impact of cancer (regardless of primary site) on patients’ routine activities. Readers are directed to the Quality of Life Instruments Database (www.proqolid.org) for guidance when selecting an instrument for quality-of-life measurement in studies of prostate or other cancers.

Selecting a Health-Related Quality-of-Life Instrument

Investigators or clinicians considering measuring HRQOL in a clinical study or in clinical practice should base their choice of instrument(s) on the particular population being studied and the clinical questions being asked. Using previously validated instruments, to the extent to which they are applicable and appropriate, obviates the need for an arduous process of instrument development and validation. Use of a general and a disease-specific module in combination is suitable for most studies. However, if a particular domain (e.g., pain) is the focus of the study, specific, expanded questionnaires focusing on the area of interest should be sought. Respondent burden needs to be considered, particularly for longitudinal studies in which subjects will complete the same instruments multiple times. Pretesting of instruments that will be used in clinical studies is advisable.

TABLE 4-2 International Consultation on Incontinence Questionnaire (ICIQ) Modules

MODULE	QUESTIONNAIRE FROM WHICH DERIVED	SYMPTOMS ASSESSED	REFERENCE
ICIQ-FLUTS	BFLUTS Short Form (Brookes et al, 2004)	Female urinary	Brookes et al, 2004
ICIQ-FLUTS Long Form	BFLUTS (Jackson et al, 1996)	Female urinary	Jackson et al, 1996
ICIQ-MLUTS	ICSmale Short Form (Donovan et al, 2000)	Male urinary	Donovan et al, 2000
ICIQ-MLUTS Long Form	ICSmale (Donovan et al, 1996)	Male urinary	Donovan et al, 1996
ICIQ-LUTSqol	KHQ (Kelleher et al, 1997)	Urinary quality of life	Kelleher et al, 1997
ICIQ-N	ICSmale (Donovan et al, 1996)	Nocturia	Donovan et al, 1996
ICIQ-Nqol	BFLUTS (Jackson et al, 1996)	Nocturia quality of life	Jackson et al, 1996
ICIQ-VS	N-QOL (Abraham et al, 2004)	Nocturia quality of life	Abraham et al, 2004
ICIQ-B		Vaginal	Abrams et al, 2006
ICIQ-FLUTSsex		Bowel	Abrams et al, 2006
ICIQ-MLUTSsex	BFLUTS (Jackson et al, 1996)	Female sexual related to urinary symptoms	Jackson et al, 1996
ICIQ-OAB	ICSmale (Donovan et al, 1996)	Male sexual related to urinary symptoms	Donovan et al, 1996
	ICSmale (Donovan et al, 1996)	Overactive bladder	Donovan et al, 1996
	BFLUTS (Jackson et al, 1996)		Jackson et al, 1996
ICIQ-OABqol	OABq (Coyne et al, 2002)	Overactive bladder quality of life	Coyne et al, 2002
ICIQ-UI Short Form		Urinary incontinence	Abrams et al, 2006

Psychometric Validation of New Health-Related Quality-of-Life Instruments

The development and validation of new instruments and scales is a long and arduous process. When scales and instruments are developed, they are first pilot tested to ensure that the target population can understand and complete them with ease. Pilot testing is usually preceded by work with focus groups, and includes formal cognitive testing. Pilot testing can reveal problems that might otherwise go unrecognized by researchers. For example, many terms that are commonly used by medical professionals are poorly understood by patients. In fact, because the average adult reads at the fifth- to eighth-grade level, items should be drafted at no higher than an eighth-grade reading level (Paasche-Orlow et al, 2003; Osborn et al, 2007; Paasche-Orlow and Wolf, 2007, 2010; Osborn et al, 2011; Waite et al, 2013). In addition, the digital divide between those of low and high socioeconomic status should be considered (Levy et al, 2013).

Scales and instruments are also evaluated for three fundamental statistical properties—reliability, validity, and responsiveness (Litwin, 1995; Ware et al, 1996; Resnick and Nahm, 2001; DeVellis, 2011).

Reliability

Reliability (Table 4-3) refers to how free the scale is of measurement error—that is, what proportion of a patient's test score is true and what proportion is the result of chance variation. Two of the most commonly used metrics are test-retest and internal consistency reliability. *Test-retest reliability* is the most commonly used indicator of survey instrument reliability. It is measured by having the same respondents complete a survey at two different points in time to see how stable their responses are. It is a measure of how reproducible a set of results is. When measuring test-retest reliability, one must be careful not to select items or scales that measure variables likely to change over short periods of time. Variables that are likely to change over a given period of time will produce low test-retest reliability in measurement instruments. This does not mean that the survey instrument is performing poorly but simply that the attribute itself has changed.

When measuring test-retest reliability, one must also consider that individuals may become familiar with the items and answer partly on the basis of their memory of what they answered the last time. Called the *practice effect*, this presents a challenging problem to address in measures of test-retest reliability over short periods of time. As a result of the practice effect, test-retest reliability figures

can be falsely inflated. *Alternate-form reliability* provides one way to escape the problem of the practice effect. It involves using differently worded items to measure the same attribute. Questions and responses are reworded or their order is changed to produce two items that are similar but not identical. One way to test alternate-form reliability is to change the wording of the response sets without changing the meaning. Another common method to test alternate-form reliability is to change the actual wording of the items themselves.

The correlation between two data sets from the same individual is commonly known as *intraobserver reliability*. It measures the stability of responses from the same respondent and is a form of test-retest reliability. *Interobserver (inter-rater) reliability* provides a measure of how well two or more evaluators agree in their assessment of a variable. When survey instruments are self-administered and designed to measure the respondent's own behaviors or attitudes, interobserver reliability is not used. *Internal consistency reliability* is a measure of the similarity of an individual's responses across several items, indicating the homogeneity of a scale (Henson, 2001). It is applied not to single items but to groups of items that are thought to measure different aspects of the same concept.

Validity

Validity (Table 4-4) refers to how well the item, scale, or instrument measures the attribute it is intended to measure. Validity has three general forms: content, criterion, and construct. *Content validity*, sometimes referred to as *face validity*, involves a subjective assessment of the scope and completeness of a scale and is usually measured in the early stages of an instrument's development by experts and through use of patient focus groups. The assessment of content validity typically involves an organized review of an instrument's contents to ensure that it includes everything it should and does not include anything it should not. *Criterion validity* is a more quantitative approach to assessing the performance of scales and instruments. It requires the correlation of scale scores with results from other established tests (concurrent validity) or with future measurable outcomes (predictive validity). *Concurrent validity* requires that the survey instrument in question be judged against some other method that is acknowledged as a gold standard for assessing the same variable. It may be a published psychometric index, a scientific measurement of some factor, or another generally accepted test. *Predictive validity* is the ability of a survey instrument to forecast future events, behaviors, attitudes, or outcomes. It may be used during the course of a study to predict response to a stimulus, success of an intervention, or time to a medical end point. *Construct*

TABLE 4-3 Reliability Assessments for Health-Related Quality-of-Life Instruments

TYPE OF RELIABILITY	CHARACTERISTICS	COMMENTS
Test-retest	Measures the stability of responses over time, typically in the same group of respondents	Requires administration of survey to a sample at two different and appropriate points in time. Time points that are too far apart may produce diminished reliability estimates that reflect actual change over time in the variable of interest.
Intraobserver	Measures the stability of responses over time, in the same individual respondent	Requires completion of a survey by an individual at two different and appropriate points in time. Time points that are too far apart may produce diminished reliability estimates that reflect actual change over time in the variable of interest.
Alternate-form	Uses differently worded stems or response sets to obtain the same information about a specific topic	Requires two items in which the wording is different but aimed at the same specific variable and at the same vocabulary level.
Internal consistency	Measures how well several items in a scale vary together in a sample	Usually requires a computer and statistician to carry out calculations.
Interobserver	Measures how well two or more different respondents rate the same phenomenon	May be used to demonstrate reliability of a survey or may itself be the variable of interest in a study.

TABLE 4-4 Validity Assessments for Health-Related Quality-of-Life Instruments

TYPE OF VALIDITY	CHARACTERISTICS	COMMENTS
Content	Formal expert review of how good an item or series of items appear	Usually assessed by individuals with expertise in some aspect of the subject under study
Criterion: Concurrent	Measures how well the item or scale correlates with gold-standard measures of the same variable	Requires the identification of an established, generally accepted gold standard
Criterion: Predictive	Measures how well the item or scale predicts expected future observations	Used to predict outcomes or events of significance that the item or scale might subsequently be used to predict
Construct	A theoretic measure of how meaningful a survey instrument is, usually after years of experience by numerous investigators	Not easily quantifiable

validity is the most valuable yet most difficult way of assessing a survey instrument. It is a measure of how meaningful the scale or survey instrument is when in practical use.

Responsiveness

Responsiveness of an HRQOL instrument refers to how sensitive the scales are to change over time (Murawski and Miederhoff, 1997; Terwee et al, 2003). That is, a survey may be reliable and valid when used at a single point in time, but in some circumstances it must also be able to detect meaningful improvements or decrements in quality of life during longitudinal studies. The instrument must “react” in a time frame that is relevant for patients over time. Because HRQOL may change over time, longitudinal measurement of these outcomes is important. In urology, widely used instruments such as the University of California–Los Angeles Prostate Cancer Index and the National Institutes of Health Chronic Prostatitis Symptom Index are highly responsive to clinical changes.

Comparison Groups

Prospective, longitudinal data collection beginning at baseline before treatment is always best because this approach may reveal time-dependent evolution of HRQOL domains (Litwin et al, 2001; Malcolm et al, 2010; Reeve et al, 2012). Patients may then serve as their own controls. Assessing HRQOL at baseline before treatment allows for the inclusion of baseline age- or comorbidity-related changes that should not be attributed to treatment. This approach facilitates the stratification of discriminants from determinants of HRQOL.

Caveats on the Collection of Health-Related Quality-of-Life Data

The overarching goals of HRQOL research are summarized in Box 4-1. Although there are some single instruments that are multidimensional, many quality-of-life researchers have endorsed a “battery approach,” in which the various components of HRQOL are measured with different scales to ensure that each domain receives adequate attention. Longer instruments can provide greater precision, but they also increase the chance that patients will tire of the exercise and not provide reliable or valid answers. Hence, shorter instruments are usually preferable when one is performing HRQOL measurements in such circumstances. In general, it is easier and more efficient to use established instruments that have already undergone psychometric validation. Use of HRQOL data collected using published instruments allows the researcher to compare the study results with data from other samples or diverse populations with various chronic diseases. Nevertheless, sometimes it is necessary to develop new questionnaire items to ensure that a particular concept is adequately evaluated. Under such circumstances new

BOX 4-1 Quality-of-Life Objectives in Research and Practice

- To assess overall treatment efficacy including subjective morbidity
- To help determine whether the goals of treatment have been met
- To educate patients and clinicians about the full spectrum of treatment outcomes
- To facilitate medical decision making
- To provide the defining issue if treatments are otherwise equivalent

scales can be tested for reliability and validity during the course of data collection.

HEALTH SERVICES RESEARCH METHODOLOGIES

Retrospective Review of the Medical Record

The image of an “outcomes” researcher retrospectively reviewing charts to understand variations in an outcome of interest originated in the Crimean War, when Florence Nightingale documented high death rates among injured soldiers treated at overcrowded facilities with poor hygiene (Cook, 1914; Kopf, 1916). Although retrospective chart review is only one arrow in a health services researcher’s quiver, it can unearth important health systems failings, such as poor follow-up of positive fecal occult blood testing results at the time of hospital admission (Scales et al, 2006). Such failings can then be targeted for quality improvement interventions.

Secondary Data Analysis

Secondary data involve an analysis of information collected by someone other than the researcher. Examples include hospital and outpatient claims, censuses, and pharmaceutical records, as well as qualitative data obtained by a third party. One of the main benefits of secondary data analyses is that the data have already been collected; a corollary downfall is that the researcher is limited to those data. In selecting an optimal data set, criteria to consider include availability of information regarding the data collection process, issues related to study design, the need for adjustment for sample design characteristics, the relative robustness of the data set, and the time required to procure and analyze the data (Litwin et al, 2005b). If several different data sets are chosen for a common venture, selecting complementary rather than overlapping data sets affords a view through the broadest

possible lens. One limitation of secondary data analysis is the reliance of accurate coding, without which overestimation or underestimation is possible.

Community-Partnered Participatory Research

Community-partnered participatory research involves a collaborative process among researchers, communities, and others; all partners collaborate and are valued equally (Humphreys et al, 2008; Chung et al, 2009; Khodyakov et al, 2009; Wells and Jones, 2009; Chung et al, 2010, 2011; Lizaola et al, 2011; Hunt et al, 2012; Wells et al, 2013a, 2013b). Its goal is to develop, implement, and disseminate work that will benefit a community. Community strengths can then be celebrated, and community needs not only identified, but also addressed from within. For example, interventions in which urologists partner with barbershops help promote prostate cancer knowledge and, when appropriate, screening (Relford et al, 2010). Results are then shared with the community to promote ongoing partnerships and build trust and capacity. Interventions do not need to focus on disadvantaged communities; when researchers collaborate with physician practices and feed findings back to those groups, substantial improvement can be made in clinical care, including use of immediate intravesical therapy after resection for non-muscle invasive bladder cancer and appropriate metastatic workup for men with prostate cancer (Miller et al, 2010; Barocas et al, 2013b).

Implementation Science

In medicine, translating good evidence into broadly implemented practice takes, on average, 17 years (Pfeffer and Sutton, 2006). Delays in uptake exist in medical treatment to facilitate passage of urinary stones (Hollingsworth et al, 2006; Scales et al, 2007), chemoprevention of prostate cancer (Hamilton et al, 2010), and weight loss for urinary incontinence (Bland et al, 2003; Subak et al, 2009; Wing et al, 2010; Holroyd-Leduc et al, 2011; St Sauver et al, 2011; Phelan et al, 2012). Implementation science seeks to compress the timeline. Implementation research studies methods for systematically adopting evidence-based practices into routine care, to improve quality and effectiveness (Stetler et al, 2008; Proctor et al, 2009; Eccles et al, 2012; Methodology Committee of the Patient-Centered Outcomes Research Institute, 2012; Yano et al, 2012; Meissner et al, 2013). It encompasses field research, clinical work, communities, and health policy. In surgery, implementation of evidence-based infection control processes using comprehensive unit-based safety programs reduces rates of surgical site infections (Wick et al, 2012). For urologists, evidence-based guidelines abound (Davis et al, 2012; Sharlip et al, 2012; Carter et al, 2013a; Cookson et al, 2013; Donat et al, 2013), but broad implementation remains an unmet challenge (Chamie et al, 2011; Chamie and Litwin, 2011; Chamie et al, 2012b; Strobe et al, 2011, 2012). Implementation strategies may focus on small-group continuing education with urologists and primary care providers, lectures, patient education materials, and public endorsement by national figures (Puech et al, 1998). Engagement of all stakeholders during guideline development and dissemination is key (Smith and Hillner, 2001).

Qualitative Research

Qualitative research involves interviews, group discussions, field notes, and observations. It allows exploration of aspects of care that may not be accessible from other data sources, and issues may be unearthed that were not readily apparent at the beginning of data collection. Qualitative methods can also be used to explore options for overcoming obstacles, such as renegotiating masculine identity after treatment for prostate cancer (Maliski et al, 2008). Methodologic rigor must be applied to data collection and analysis, and data analysis options include coding, recursive abstraction, interpretive techniques, and mechanical techniques (Erickson, 2012).

FUTURE IMPLICATIONS

Balancing Analysis of Current Shortcomings with Interventions for Change

That current urologic care leaves significant space for improvement has now been well documented. Likewise, disparities in quality of care often overshadow the more salient understanding that care is often mediocre, even in the best circumstances, and must be improved for all individuals. Although further analyses of shortcomings and disparities are important, the most pressing need is development and broad implementation of interventions that can improve care. For example, a novel method of patient preference elicitation using conjoint analysis improves decision-making quality in men with prostate cancer (Saigal et al, 2012). Developing similar interventions and identifying strategies to broadly implement them will allow urology to remain at the forefront of health care innovation and value.

Patient-Centeredness and Comparative Effectiveness

Comparative effectiveness research uses outcomes data to guide health care policy. The American Recovery and Reinvestment Act of 2009 invested \$1.1 billion to fund comparative effectiveness research (American Recovery and Reinvestment Act, 2009), and the recently enacted Patient Protection and Affordable Care Act formalized a private, nonprofit Patient-Centered Outcomes Research Institute (www.pcori.org) to equitably distribute funding (Selby et al, 2012). The allocated funds target not only reviews of existing evidence, but also new prospective, randomized trials.

Evidence-Based Health Care Policy

To maintain control over treatment decisions, urologists must work fastidiously to improve value and ensure broad implementation of evidence-based practices. For instance, if PSA screening is to continue, more nuanced strategies must be implemented to minimize overdiagnosis and overtreatment (Gulati et al, 2013). Policy makers can use several levers to encourage evidence-based care. For example, when reimbursement levels were high, androgen deprivation therapy was overused in treatment of localized prostate cancer (Cooperberg et al, 2003; Shahinian et al, 2005a; Sharifi et al, 2005; Badiozamani et al, 2009), despite well documented noxious effects (Potosky et al, 2002; Shahinian et al, 2005b; Saigal et al, 2007). Inappropriate use of androgen deprivation fell significantly after the Medicare Modernization Act lowered reimbursement (Elliott et al, 2010; Shahinian et al, 2010; Gilbert et al, 2011).

Maximizing Value

Ultimately, a urologist cares for an individual, not merely that individual's urologic needs. Whereas organizations such as the U.S. Food and Drug Administration (FDA) may approve a medication or device if it is "safe and effective" (Meadows, 2002; Institute of Medicine, 2011), physicians are held to a higher standard. We must consider not only whether a drug extends life by 3 to 5 months (Kantoff et al, 2010; de Bono et al, 2011; Fizazi et al, 2011; Cabot et al, 2012; Parker et al, 2013), but whether use of the drug is sensible in the context of competing priorities. Examples of alternative investments include early childhood and depression: each dollar invested in a child yields \$7 in return (Campbell and Ramey, 1994; Clarke and Campbell, 1998; Campbell et al, 2012), and of all socioeconomic and clinical variables, depression is singly linked with health (Covinsky et al, 1997a; Jackson-Triche et al, 2000) and wealth (Wells et al, 2000; Beddington et al, 2008). As our population ages (Vincent and Velkoff, 2010), urologists are uniquely empowered to continue to lead the effort to maximize value and shape rational policies that will make each person as healthy and happy as possible.

KEY POINTS

- Health services research focuses on access to care, cost of care, quality of care, health systems, and population health.
- The “value” of a health care service or intervention is defined as patient-centered health outcomes divided by cost. Considering cost in the context of value can help policy makers decide which interventions should be amplified and which may be reduced.
- That variation in health care spending does not correlate with outcomes suggests that good outcomes can be achieved with lowered cost, and that current spending can be targeted more thoughtfully. In urology, significant hospital-level variation exists in outcomes and readmission after surgery.
- Quality of care research evaluates “the degree to which health services for individuals and populations increase the likelihood of desired health outcomes and are consistent with current professional knowledge.” Descriptive quality measures abound, but for quality metrics to affect outcomes, they must be based on solid evidence, be measurable, and have resources devoted to tracking and improving them.
- Health-related quality of life (HRQOL) encompasses a wide range of human experience including the daily necessities of life such as food and shelter, intrapersonal and interpersonal responses to illness, and activities associated with professional fulfillment and personal happiness.
- To maintain control over treatment decisions, urologists must work fastidiously to improve value and ensure broad implementation of evidence-based practices.

Core Principles of Perioperative Care

Manish A. Vira, MD, and Joph Steckel, MD, FACS

Preoperative Evaluation

Presurgical Testing

Surgical Risk Evaluation

Optimization of Comorbid Illness

Special Populations

Preparation for Surgery

Anesthetic Considerations

Blood Products

Patient Environment

Abdominal Incisions and Wound Closure

While the practice of urology continues to move toward office-based and nonsurgical treatments, the diversity of genitourinary disease requires that the practicing urologist be familiar with perioperative surgical principles to improve clinical care. This chapter provides the reader with basic tools to understand the preoperative assessment, intraoperative techniques, and postoperative management necessary to promote a culture of patient safety and optimal surgical outcomes.

PREOPERATIVE EVALUATION

The perioperative management of patients undergoing urologic surgery continues to evolve. Over the past two decades, the economics of health care has added increasing pressure for more outpatient surgery, decreased hospital stays, and decreased complication rates. Furthermore, the acuity of surgical patients is increasing in that patients are older with more significant comorbidities. It has become standard for patients undergoing even the most sophisticated and complex urologic procedures in the hospital to be admitted on the same day as the surgery. **Therefore the urologic surgeon is responsible for ensuring that the patient has been thoroughly evaluated by the other physicians on the health care team and arrives in the operating room in the most optimized medical condition.** The preoperative use of appropriate medical specialist consultations will result in improved patient safety and obviate the need for unnecessary cancelled surgeries resulting from the inadequacy of medical optimization.

PRESURGICAL TESTING

The goal of presurgical testing is to identify an undiagnosed comorbidity, an undertreated medical problem, or a significant exacerbation of existing comorbid illness that may affect the operative outcome (Townsend et al, 2008). Ideally, the preoperative evaluation should be individualized on the basis of age, history, physical examination findings, and the surgical procedure to be performed. Although most hospitals or ambulatory surgery centers have requirements for baseline evaluation, routine testing has never been shown to be cost-effective. In fact, the results of routine testing are less predictive of perioperative morbidity than the American Society of

Anesthesiologists (ASA) status or the American Heart Association (AHA) and American College of Cardiology (ACC) guidelines for surgical risk. A recent systematic review found no evidence to support routine preoperative testing in patients undergoing noncardiac elective surgery (Johansson et al, 2013). Most commonly, presurgical testing includes complete blood count (CBC); basic metabolic panel (BMP); prothrombin time (PT), partial thromboplastin time (PTT), and international normalized ratio (INR) (controversial); electrocardiogram (ECG); and chest radiograph. The routine ordering of a PT/PTT in a patient not currently on warfarin or in a patient without a prior history of increased bleeding with other surgical procedures is controversial, and these tests can be omitted in the majority of patients. **Any woman of childbearing age, unless the ovaries or uterus have been previously surgically removed, must undergo a urine pregnancy test on the morning of surgery** (Halaszynski et al, 2004). The value of a preoperative ECG in identification of underlying acute cardiac disease and prediction of perioperative cardiac morbidity is also controversial. Some studies have shown that ECG abnormalities have no significant predictive value (Goldman et al, 1978), whereas others found that an abnormal ECG was the best diagnostic predictor of an adverse cardiac event (Carliner et al, 1985). Nonetheless, current recommendations, in general, suggest that a preoperative ECG be obtained from patients older than 40 years or those with a history of any cardiac disease. Similarly, the routine preoperative use of a chest radiograph, in the absence of preexisting cardiopulmonary disease, is not indicated. Overall, even an ASA Task Force on Preanesthesia Evaluation could not make firm recommendations other than “preoperative tests may be ordered, required, or performed on a selective basis for purposes of guiding or optimizing perioperative management” (Practice advisory for preanesthesia evaluation, 2002).

SURGICAL RISK EVALUATION

American Society of Anesthesiologists Classification and Risk Stratification

Approximately 27 million patients undergo surgery each year in the United States, and 8 million (30%) have significant coronary artery disease or other cardiac comorbidities. Appropriately,

the cardiovascular system is targeted during the preoperative assessment of patients. The ASA classification was first developed in 1961 and has been revised to categorize risk into six stratifications (Box 5-1).

The goal of the classification system is to assess the overall physical status of the patient before surgery (not to assess surgical risk), and although quite subjective, it remains a significant independent predictor of mortality (Davenport et al, 2006). Other tools to assess the preoperative risks were developed by multivariate statistical analysis of patient-related factors correlated with surgical outcomes. One such scoring system, Goldman's criteria (Table 5-1), assigns points to easily reproducible characteristics. The points are then added to compute the perioperative risk of cardiac-related complications. Another system, the Cardiac Risk Index, simplified this concept; it uses only six predictors to estimate cardiac complication risk in noncardiac surgical patients (Table 5-2) (Akhtar and Silverman, 2004).

Cardiac Evaluation

The preoperative cardiac evaluation, which consists of an initial history and physical examination and ECG, attempts to identify potential serious cardiac disorders such as coronary artery disease, heart failure, symptomatic arrhythmias, the presence of a pacemaker or implantable defibrillator, or a history of orthostatic hypotension (Eagle et al, 1996). Furthermore, it is essential

BOX 5-1 American Society of Anesthesiologists (ASA) Classification

- ASA Class I—Normal healthy patient
- ASA Class II—Patient with mild systemic disease
- ASA Class III—Patient with severe systemic disease that limits activity but is not incapacitating
- ASA Class IV—Patient who has incapacitating disease that is a constant threat to life
- ASA Class V—Moribund patient not expected to survive 24 hours with or without an operation
- ASA Class VI—A declared brain-dead patient whose organs are being removed for donor purposes
- ASA Class E—In the event of emergency surgery, an E is added after the Roman numeral (in I through V classes)

TABLE 5-1 Goldman's Cardiac Risk Index

PATIENT RISK FACTORS	POINTS
Third heart sound or jugular venous distention	11
Recent myocardial infarction	10
Nonsinus rhythm or premature atrial contraction on electrocardiogram	7
More than five premature ventricular contractions	7
Age older than 70 yr	5
Emergency operations	4
Poor general medical condition	3
Intrathoracic, intraperitoneal, or aortic surgery	3
Significant valvular aortic stenosis	3
For noncardiac surgery, the risk of cardiac complications is:	
• 6-12 points = 7% risk	
• 13-25 points = 14% risk	
• >26 points = 78% risk	

Modified from Akhtar S, Silverman DG. Assessment and management of patients with ischemic heart disease. Crit Care Med 2004;32:S126-36.

to define the severity and stability of existing cardiac disease before surgery. Cardiac-specific risk is also altered by the patient's functional capacity, age, and other comorbid conditions such as diabetes, peripheral vascular disease, renal dysfunction, and chronic obstructive pulmonary disease (COPD). The ACC and AHA recently collaborated to develop guidelines regarding perioperative cardiac evaluation before surgery (Fleisher et al, 2007a). In general, the guidelines use three categories of clinical risk predictors: clinical markers, functional capacity, and type of surgical procedure (Eagle et al, 2002).

Clinical Markers

The major clinical predictors of increased perioperative cardiovascular risk are a documented acute myocardial infarction less than 7 days previously, a recent myocardial infarction (defined as at least 7 days but less than 1 month before surgery), unstable angina, evidence of any ischemic burden by clinical symptoms or noninvasive testing, decompensated heart failure, significant arrhythmias, and severe valvular disease. Intermediate predictors include mild angina, previous myocardial infarction by history or pathologic Q waves, compensated heart failure, diabetes, or renal insufficiency (creatinine >2 mg/dL). Minor predictors of risk are advanced age, abnormal ECG, rhythms other than sinus (i.e., atrial fibrillation), history of stroke, or uncontrolled systemic hypertension. The historical dictum suggesting that elective surgery after a myocardial infarction be performed after a 3- to 6-month interval is now currently avoided (Tarhan et al, 1972). The ACC cardiovascular database committee stratifies risk on the basis of the severity of the myocardial infarction and the likelihood of reinfarction based on a recent exercise stress test. However, in the absence of adequate clinical trials on which to base firm recommendations, it is reasonable to wait 4 to 6 weeks after myocardial infarction to perform elective surgery.

Functional Capacity

Functional capacity, or one's ability to meet aerobic demands for a specific activity, is quantified as metabolic equivalents (METs). For example, a 4-MET demand is comparable with a patient's ability to climb two flights of stairs. This simple measurement continues to be an easy and inexpensive method to determine a patient's cardiopulmonary functional capacity (Biccard, 2005). The Duke Activity Status Index (Table 5-3) allows the physician to easily determine a patient's functional capacity (Hlatky et al, 1989). In general, a capacity of 4 METs indicates no further need for invasive cardiac evaluation.

Surgery-Specific Cardiac Risk

Two important factors determine the surgery-specific cardiac risk: the type of surgery and the degree of hemodynamic stress.

TABLE 5-2 Modified Cardiac Risk Index

PATIENT RISK FACTORS	POINTS
Ischemic heart disease	1
Congestive heart failure	1
Cerebral vascular disease	1
High-risk surgery	1
Preoperative insulin treatment for diabetes	1
Preoperative creatinine ≥ 2 mg/dL	1
Each increment in point increases risk of perioperative cardiovascular morbidity.	

Modified from Akhtar S, Silverman DG. Assessment and management of patients with ischemic heart disease. Crit Care Med 2004;32:S126-36.

TABLE 5-3 Duke Activity Status Index*

ACTIVITY	YES	NO
Can you take care of yourself (eating, dressing, bathing, or using the toilet)?	2.75	0
Can you walk indoors such as around your house?	1.75	0
Can you walk a block or two on level ground?	2.75	0
Can you climb a flight of stairs or walk up a hill?	5.50	0
Can you run a short distance?	8.00	0
Can you do light work around the house such as dusting or washing dishes?	2.70	0
Can you do moderate work around the house such as vacuuming, sweeping floors, or carrying in groceries?	3.50	0
Can you do heavy work around the house such as scrubbing floors or lifting and moving heavy furniture?	8.00	0
Can you do yardwork such as raking leaves, weeding, or pushing a power mower?	4.50	0
Can you have sexual relations?	5.25	0
Can you participate in moderate recreational activities such as golf, bowling, dancing, doubles tennis, or throwing a baseball or football?	6.00	0
Can you participate in strenuous sports such as swimming, singles tennis, football, basketball, or skiing?	7.50	0
Duke activity status index (DASI) = SUM (values for all 12 questions).		
Estimated peak oxygen uptake ($\dot{V}O_{2peak}$) in mL/min = $0.43 \times$ (DASI) + 9.6.		
$\dot{V}O_{2peak}$ mL/kg/min – 0.286 (mL/kg/min) ⁻¹ = METs		

*The most widely recognized measure of cardiorespiratory fitness is maximal oxygen consumption ($\dot{V}O_{2peak}$) measured in mL/kg/min. The Index score correlates directly with $\dot{V}O_{2peak}$ and therefore is an indirect measure of maximal METs.

Modified from Hlatky MA, Boineau RE, Higginbotham MB, et al. A brief self-administered questionnaire to determine functional capacity (the Duke Activity Status Index). *Am J Cardiol* 1989;64:651–4.

Surgery-specific risk is stratified into high-, intermediate-, and low-risk procedures. High-risk procedures include both major emergent surgery, particularly in the elderly, and surgery associated with increased operative time resulting in large fluid shifts or blood loss. Intermediate risk procedures include intraperitoneal surgery, laparoscopic procedures, and robotic-assisted laparoscopic surgeries. Low-risk procedures include endoscopic procedures or superficial surgeries (i.e., not involving entrance into a body cavity) (Eagle et al, 2002).

Pulmonary Evaluation

Preoperative pulmonary evaluation is important in all urologic procedures but critical in those surgeries involving the thoracic or abdominal cavities. These procedures, which include intra-abdominal, laparoscopic, or robotic surgeries, can decrease pulmonary function and predispose to pulmonary complications. Accordingly, it is wise to consider pulmonary functional assessment in patients who have significant underlying medical disease, significant smoking history, or overt pulmonary symptoms. Pulmonary function tests that include a forced expiratory volume in 1 second (FEV₁), forced vital capacity, and the diffusing capacity of carbon monoxide are quite easily performed and provide a preoperative baseline. Patients with an FEV₁ of less than 0.8 L/sec or 30% of predicted are at high risk for complications

(Arozullah et al, 2003). Specific pulmonary risk factors include COPD, smoking, preoperative sputum production, pneumonia, dyspnea, and obstructive sleep apnea. It has been shown that smokers have a fourfold increased risk for postoperative pulmonary morbidity and as high as a 10-fold higher mortality rate (Fowkes et al, 1982). In general, it is interesting to note that patients with restrictive pulmonary disease fare better than those with obstructive pulmonary disease because the former group maintains an adequate maximal expiratory flow rate, which allows for a more effective cough with less sputum production (Pearce and Jones, 1984). In addition to the specific pulmonary risk factors, general factors contribute to increased pulmonary complications such as increased age, lower serum albumin levels, obesity, impaired sensorium, previous stroke, immobility, acute renal failure, and chronic steroid use.

Hepatobiliary Evaluation

Because the survival of patients with advanced liver disease has improved over the past decade, surgery is being performed more frequently in these patients. Furthermore, patients with mild to moderate hepatic disease are often asymptomatic. These patients need to be identified and evaluated before surgery. Patients are usually aware of a prior diagnosis of hepatitis, and they should be questioned regarding the timing of diagnosis and the precipitating factors. This history is particularly important if a member of the health care team is inadvertently stuck with a needle or scalpel during the surgical procedure. A review of systems should include questions regarding pruritus, excessive bleeding, abnormal abdominal distention, and weight gain. On physical examination, jaundice and scleral icterus may be evident with serum bilirubin levels higher than 3 mg/dL. Skin changes such as caput medusae, palmar erythema, spider angiomas, and clubbing all indicate hepatic dysfunction. Severe manifestations include abdominal distention, encephalopathy, asterixis, or cachexia. Again, identification of underlying hepatic illness is important in the preoperative risk assessment of the patient. Although the estimation of perioperative mortality is limited by the lack of high-quality clinical studies, the use of the Child classification and Model for End-Stage Liver Disease (MELD) score offers a reasonable estimation.

The Child classification assesses perioperative morbidity and mortality in patients with cirrhosis and is based on the patient's serum markers (bilirubin, albumin, PT) and severity of clinical manifestations (i.e., encephalopathy and ascites). Mortality risk for patients undergoing surgery stratified by Child class is as follows: Child Class A—10%, Child Class B—30%, and Child Class C—76% to 82%. The Child classification also correlates with the frequency of complications such as liver failure, encephalopathy, bleeding, infection, renal failure, hypoxia, and intractable ascites. Independent risk factors other than the Child class that can increase the mortality rate in patients with liver disease include emergency surgery and COPD (Pearce and Jones, 1984; O'Leary et al, 2009).

The MELD score is perhaps a more accurate assessment of perioperative mortality in patients with hepatic dysfunction. The score is derived from a linear regression model based on serum bilirubin, creatinine levels, and the INR. It is more accurate than the Child classification in that it is objective, gives weights to each variable, and does not rely on arbitrary cutoff values (Teh et al, 2007). Clinicians can use a website (<http://mayoclinic.org/meld/mayomodel9.html>) to calculate the 7-day, 30-day, 90-day, 1-year, and 5-year surgical mortality risk on the basis of the patient's age, ASA class, INR, serum bilirubin, and creatinine levels. A recent study also found that MELD score was tightly correlated with 30-day mortality risk in all patients undergoing colorectal surgery regardless of the presence of liver disease (Hedrick et al, 2013). Taken together, the Child classification and the MELD score complement each other and provide an important assessment of the risk of surgery in cirrhotic patients (O'Leary and Friedman, 2007; O'Leary et al, 2009).

OPTIMIZATION OF COMORBID ILLNESS

Just as adequate preoperative evaluation is important, optimization of comorbid illness is critical in reducing perioperative morbidity and mortality. With regard to cardiac disease, many studies have evaluated the prophylactic use of nitrates, calcium-channel blockers, and β -blockers for patients who are at risk for perioperative myocardial ischemia. Only β -blockade has been shown to improve outcomes (Pearse et al, 2004). In a landmark study, Mangano and colleagues reported in the *New England Journal of Medicine* that there was an improvement in outcomes with the prophylactic use of atenolol in patients undergoing vascular surgery (Mangano et al, 1996). Similarly, a retrospective, cooperative group study of more than half a million patients showed that perioperative β -blockade is associated with a reduced risk of death among high-risk patients undergoing major noncardiac surgery (Lindenauer et al, 2005). In addition to β -blockade, the concept of goal-directed therapy, employing the judicious use of fluids, inotropes, and oxygen therapy to achieve therapeutic goals, may further reduce perioperative risk (Pearse et al, 2004). This concept was validated by Shoemaker, who reported an impressive reduction in mortality from 28% to 4% ($P < .02$) when goal-directed therapy was used (Shoemaker et al, 1988).

Specific preoperative interventions can decrease pulmonary complications. Smoking must be discontinued at least 8 weeks before surgery to achieve a risk reduction. Patients who discontinue smoking less than 8 weeks before surgery may actually have a higher risk of complication because the acute absence of the noxious effect of cigarette smoke decreases postoperative coughing and pulmonary toilet. **However, patients who stop smoking at least 8 weeks preoperatively will significantly lower their complication rate, and patients who have ceased smoking for more than 6 months have a pulmonary morbidity comparable with that of nonsmokers (Warner et al, 1989).** The use of preoperative bronchodilators in COPD patients can dramatically reduce postoperative pulmonary complications. Aggressive treatment of preexisting pulmonary infections with antibiotics, as well as the pretreatment of asthmatic patients with steroids, is essential in optimizing pulmonary performance. Likewise, the use of epidural and regional anesthetics, vigorous pulmonary toilet, rehabilitation, and continued bronchodilation therapy are all beneficial (Arozullah et al, 2003).

As with cardiopulmonary comorbidities, the preoperative management and optimization of diabetic patients are quite important. Perioperative hyperglycemia can lead to impaired wound healing and a higher incidence of infection (Golden et al, 1999). Hypoglycemia in an anesthetized or sedated diabetic patient may be unrecognized and carries its own significant risks. **Non-insulin-dependent diabetic patients may need to discontinue long-acting hypoglycemics because of this risk of intraoperative hypoglycemia. Shorter-acting agents or sliding scale insulin regimens are preferable, in general.** It is recommended that blood glucose levels be controlled between 80 and 250 mg/dL. Frequent fingerstick glucose checks and a sliding scale short-acting insulin regimen are used in the postoperative period. Once the patient is eating, the usual insulin regimen can be resumed. Patients who monitor their diabetes with the use of insulin pumps should continue their basal insulin infusions on the day of surgery. The pump is then used to correct the glucose level as it is measured. It is important to know the sensitivity factor that corrects the glucose so that the patient's sugars can be managed in the operating room (Townsend et al, 2008).

Patients with either hyperthyroidism or hypothyroidism should be evaluated by an endocrinologist, and surgery should be deferred until a euthyroid state has been achieved. **The greatest risk in the hypothyroid patient is thyrotoxicosis or thyroid storm, which can manifest with fevers, tachycardia, confusion, and cardiovascular collapse.** Atrial fibrillation may also be present in 20% of hyperthyroid patients (Klein and Ojamaa, 2001). With regard to hyperthyroidism, careful attention should be given to the airway because the trachea can be compressed or deviated by a large goiter. In general, antithyroid medications such as propylthiouracil or

methimazole, as well as β -blockers, are continued on the day of surgery. In the event of thyroid storm, iodine and steroids may be necessary (Schiff and Welsh, 2003). Hypothyroidism is usually associated with an increased sensitivity to medications such as anesthetic agents and narcotics. Severe hypothyroidism can be associated with myocardial dysfunction, coagulopathy, electrolyte imbalance, and a decreased gastrointestinal (GI) motility. Symptoms include lethargy, cold intolerance, hoarseness, constipation, dry skin, and apathy. The decrease in metabolic rate produces periorbital edema, thinning of the eyebrows, brittle hair, dry skin, hyperthermia, bradycardia, and a prolonged relaxation of the deep tendon reflexes (Murkin, 1982). Once the diagnosis has been confirmed by a low thyroxine level and an elevated thyroid stimulating hormone level, thyroid replacement with levothyroxine can be initiated (Schiff and Welsh, 2003).

The evaluation of the patient either taking corticosteroids or suspected of having an abnormal response of the hypothalamic-pituitary-adrenal (HPA) axis is also important. There is a wide variability in HPA suppression in patients receiving exogenous steroids. Nonetheless, it seems clear that the administration of oral steroids equivalent to less than 5 mg of prednisone for any duration of time does not cause clinically significant suppression of the HPA axis. **By contrast, any patient taking more than 20 mg of prednisone or its equivalent per day for more than 3 weeks or who is clinically cushingoid has probable HPA axis suppression (LaRoche et al, 1993).** HPA suppression can occur even in patients using potent topical steroids at doses of 2 g/day, as well as in patients using inhaled corticosteroids at doses of 0.8 mg/day. Although the duration of functional HPA axis suppression after glucocorticoids have been stopped is debatable, perioperative supplemental steroids are recommended for patients who have received HPA axis-suppressive doses within 1 year of surgery. A low-dose adrenocorticotrophic hormone (ACTH) stimulation test can be used to assess the HPA axis and the need for stress steroids. For patients who take 5 mg of prednisone or the equivalent each day, no supplemental steroids are necessary and the usual daily glucocorticoid dose may be given in the perioperative period. **For those in whom the HPA axis is presumed to be suppressed or is documented to be suppressed, then 50 to 100 mg of intravenous hydrocortisone is given before the induction of anesthesia and 25 to 50 mg of hydrocortisone is given every 8 hours thereafter for 24 to 48 hours until the usual steroid dose can be resumed.** Minor procedures under local anesthesia do not require stress-dose steroids (Schiff and Welsh, 2003).

SPECIAL POPULATIONS

Elderly

It is estimated that by 2050 the number of Americans over the age of 65 will more than double to 89 million individuals, with more than 20% over the age of 85 (Jacobsen et al, 2011). Accordingly, octogenarians and nonagenarians are undergoing an increasing number of surgeries annually. Because of elderly patients' special physiologic, pharmacologic, and psychological needs, a unique set of health care challenges is encountered. It is still unclear whether advanced age independently predicts surgical risk or whether it is coexisting medical conditions that adversely affect surgical outcomes. However, in a large study published by Turrentine, it was shown that increased age independently predicted morbidity and mortality (Turrentine et al, 2006). This confirmed the study by Vemuri, who also found increased age to be an independent risk factor for morbidity and mortality in patients undergoing aneurysm surgery (Vemuri et al, 2004). Within the urologic literature, Liberman and colleagues reported 90-day mortality rates after radical cystectomy in patients younger than 70 years, 70 to 80 years, and older than 80 years of 2%, 5.4%, and 9.2%, respectively (Liberman et al, 2011). The studies suggest that independent of comorbidities, perhaps the elderly patient cannot meet the increased functional demand required during the perioperative and postoperative periods. Hypertension and dyspnea were the most frequently seen comorbid risk factors in patients older than 80 years, and

preoperative transfusion history, emergency operation, and weight loss best predicted postoperative morbidity. Each 30-minute increase of operative time increased the odds of mortality by 17% in octogenarians (Turrentine et al, 2006). A unique and important factor in the perioperative care of the elderly is in the identification and prevention of delirium. Often overlooked as “sundowning,” delirium can be the first clinical sign of metabolic and infectious complications (Townsend et al, 2008).

Morbid Obesity

With the rising incidence of obesity, as well as the vast experience gathered from bariatric surgery, the care of the morbidly obese patient has been extensively studied. One must carefully weigh the risk of any surgical procedure with the natural history of the disease when deciding the optimal time of the surgery in the morbidly obese. **It is estimated that patients with a body mass index (BMI) of 45 kg/m² or higher may lose anywhere from 8 to 13 years of life expectancy** (Fontaine et al, 2003). The careful selection of the morbidly obese patient for elective surgery is of paramount importance. Cardiac symptoms such as exertional dyspnea and lower extremity edema are nonspecific in morbidly obese patients, and many of these patients have poor functional capacity. The physical examination often underestimates cardiac dysfunction in the severely obese patient. Severely obese patients with more than three coronary heart disease risk factors may require noninvasive cardiac evaluation (Poirier et al, 2009). Obesity is associated with a vast array of comorbidities. Morbidly obese patients often have atherosclerotic cardiovascular disease, heart failure, systemic hypertension, pulmonary hypertension related to sleep apnea and obesity, hypoventilation, cardiac arrhythmias, deep vein thrombosis, history of pulmonary embolism, and poor exercise capacity. There are also numerous pulmonary abnormalities that result in a ventilation-perfusion mismatch and alveolar hypoventilation. Obesity is a risk factor for postoperative wound infections, and, when appropriate, laparoscopic surgery should be considered.

Pregnancy

Urologic surgery in the pregnant woman is most commonly related to the management of renal colic and urinary tract stones. In the asymptomatic woman, the stones can be discovered during the sonographic evaluation of the fetus or during the evaluation of the pregnant woman who is experiencing renal colic. **The fetus is at the highest risk from radiation exposure from the preimplantation period to approximately 15 weeks' gestation.** Because the radiation dose that is associated with congenital malformations is 10 cGy, the evaluation of renal colic in a pregnant patient is performed usually with sonography (radiation dose with abdominal computed tomography [CT]—1 cGy; intravenous pyelogram—0.3 cGy). The indications for operative intervention in the pregnant patient are discussed elsewhere in this book. Anesthetic risks during pregnancy concern both the mother and the fetus. During the first trimester the fetus may be directly exposed to the teratogenic effects of certain anesthetic agents. Later in pregnancy, anesthesia places the mother at risk for preterm labor and the fetus at risk for hypoxemia secondary to changes in uterine blood flow and maternal acid base balance. These risks seem to be greatest during the first and third trimesters. **For semielective procedures, an attempt should be made to delay surgery until after the first trimester.** However, one must consider the continued exposure of the underlying condition in relation to the operative risks to both the mother and the fetus. **The second trimester is the safest time to perform surgery because organ system differentiation has occurred and there is almost no risk for anesthetic-induced malformation or spontaneous abortion.** When one is contemplating surgery on a pregnant patient, consultation with the obstetrician, perinatologist, and anesthesiologist is essential. These specialists will help determine the optimum technique to monitor the status of the fetus. Fetal heart rate monitors and tocometer monitoring for

uterine activity are used before and after the procedure. Postoperative pain is best managed with narcotic analgesics because they have not been shown to cause birth defects in humans when used in normal dosages. Nonsteroidal anti-inflammatory medication should be avoided because of the risk for premature closure of the ductus arteriosus. Chronic use of narcotics during pregnancy may cause fetal dependency, and it is recommended that the pregnant postsurgical patient be weaned off narcotic use as soon as possible (Mikami et al, 2008).

Nutritional Status

Malnutrition compromises host defenses and increases the risk of perioperative morbidity and mortality. Adequate nutritional status is essential for proper wound healing, management of infections, return of GI activity, and maintenance of vital organ status (McDougal, 1983). The preoperative evaluation and classification of the patient's nutritional status typically consist of the assessment of any recent weight loss and the measurement of laboratory values, such as lymphocyte count and serum albumin. A 20-pound weight loss in the preceding 3 months before surgery is considered to be a reflection of severe malnutrition. The lymphocyte count and serum albumin level reflect visceral protein status, with lower levels indicating malnutrition (Reinhardt et al, 1980). Several assessment tools have been validated to quantitate nutritional status, including the Subjective Global Assessment (<http://subjectiveglobalassessment.com>).

There are two methods for nutritional support. Total parenteral nutrition (TPN) is used for patients who are severely malnourished and who have a nonfunctioning GI tract. Several studies have shown that 7 to 10 days of preoperative parenteral nutrition improves postoperative outcome in undernourished patients (Von Meyenfeldt et al, 1992). However, its use in well-nourished or mildly undernourished patients either is of no benefit or increases risk of sepsis (**Perioperative total parenteral nutrition in surgical patients, 1991**). On the other hand, enteral nutrition has fewer complications than TPN and can provide a more balanced physiologic diet. Elemental nutrition is accomplished via a feeding tube, gastrostomy, or feeding jejunostomy. Enteral nutrition maintains the gut-associated lymphoid tissue, enhances mucosal blood flow, and maintains the mucosal barrier. There are hundreds of enteral products on the market, and most have a caloric density of 1 to 2 kcal/mL. These formulas are also lactose free and provide the recommended daily allowances of vitamins and minerals in less than 2 L/day. The patients receiving enteral feedings must be monitored for improvement in nutritional status, GI intolerance, and fluid and electrolyte imbalance. **Preoperative enteral feedings can decrease postoperative complication rates by 10% to 15% when used for 5 to 20 days before surgery** (**Guidelines for the use of parenteral and enteral nutrition, 2002**). **The guidelines recommend postoperative parenteral nutrition in patients who are unable to meet their caloric requirements within 7 to 10 days.** Just as in the perioperative state, enteral feedings are preferred over parenteral nutrition when feasible. Moreover, the routine use of postoperative TPN has not proven useful in well-nourished patients or in those with adequate oral intake within 1 week after surgery (Byers and Hameed, 2008). Complications can occur with either enteral nutrition or parenteral nutrition. Dislodgement of nasoenteral tubes and percutaneous enteral catheters can result in pulmonary and peritoneal complications. Adynamic ileus may also occur because of decreased splanchnic perfusion, sympathetic tone, or opiate use. With regard to TPN, establishing central access is associated with a significant risk of complications. These include pneumothorax or hemothorax secondary to poor line placement and chylothorax secondary to thoracic duct injury. Line sepsis is the most common complication of indwelling central catheters and necessitates catheter removal. Venous thrombosis with associated thrombophlebitis and extremity edema has been reported. Catheter thrombosis has also been reported and can be treated with thrombolytic agents (**Guidelines for the use of parenteral and enteral nutrition, 2002**).

PREPARATION FOR SURGERY

Antibiotic Prophylaxis

In 1999 the Centers for Disease Control and Prevention (CDC) issued its third report on the prevention of surgical site infections (SSIs), highlighting the importance of standardization of prophylactic treatment to prevent this universal surgical complication (Mangram et al, 1999). The report indicated that SSIs account for approximately 40% of nosocomial infections in surgical patients and potentially prolong hospital stay by 7 to 10 days. A study of national SSIs from the 2005 Healthcare Cost and Utilization Project National Inpatient Sample (HCUP NIS) calculated an increase in hospital stay of 9.7 days and in per-patient cost of \$20,892 (de Lissoy et al, 2009). This translated nationally into an additional 1 million inpatient hospital days and additional health care cost of \$1.6 billion. Bowater and colleagues published a systematic review of meta-analyses (level 1 evidence) and concluded that there was substantial evidence that antibiotic prophylaxis was an effective prevention for SSI over a wide variety of surgical procedures (Bowater et al, 2009). Given both the ethical responsibility of the surgeon to decrease surgical morbidity and the recent policy shift by the Centers for Medicare and Medicaid Services to withhold reimbursement for hospital admissions secondary to specific SSI, it is mandatory for urologists to understand the principles behind and to practice SSI prevention.

Along with antibiotic prophylaxis, proper hand washing and scrubbing and sterile preparation of the operative field have always been central to the prevention of SSI. For procedures involving the GI tract, mechanical and oral antibiotic bowel preparation had been standard practice until more recent literature, calling into question its usefulness (discussed later). Preoperative hair removal has not been associated with a decrease in SSI, but if performed, use of mechanical clippers or depilatory creams as opposed to razors is associated with a decreased risk of SSI (Wolf et al, 2008).

The risk of SSI and therefore the recommendation for antibiotic prophylaxis is composed of three risk factors: the patient's susceptibility to and ability to respond to localized and systemic infection, the procedural risk of infection, and the potential morbidity of infection. Patient-related factors, listed in Box 5-2, increase risk by decreasing natural defenses, increasing the local bacterial concentration, and/or altering the spectrum of bacterial flora. Second, surgical procedure-specific factors can affect the route of entry, site of infection, and pathogen involved. This idea was first described in the landmark study from the National Research Council and later formalized by the CDC; specifically, surgical wounds are now classified by degree of contamination (i.e., the inoculum of potential

BOX 5-2 Patient Factors That Increase the Risk of Infection

Advanced age
Anatomic anomalies
Poor nutritional status
Smoking
Chronic corticosteroid use
Immunodeficiency
Chronic indwelling hardware
Infected endogenous or exogenous material
Distant coexistent infection
Prolonged hospitalization

Data from Cruse PJ. Surgical wound infection. In: Wonsiewicz MJ, editor. Infectious disease. Philadelphia: Saunders; 1992. p. 758–64; and Mangram AJ, Horan TC, Pearson ML, et al. Guideline for prevention of surgical site infection, 1999. Hospital Infection Control Practices Advisory Committee. Infect Control Hosp Epidemiol 1999;20:250–78; quiz 279–80.

pathogen) (Box 5-3; Hart et al, 1968). To predict the risk of SSI, several scoring systems have been developed incorporating patient-related factors with wound classification. Finally, the risk to the patient from SSI is an important consideration in determining the need for prophylaxis. For example, routine cystoscopy in the evaluation of microhematuria in an otherwise young, healthy patient may not warrant prophylaxis; however, the same procedure in an elderly, insulin-dependent diabetic (immunocompromised) does warrant prophylaxis given the high likelihood that a postprocedural urinary tract infection would result in a significant deterioration in the patient's overall health. Understanding the three factors together then allows the urologist to make a rational decision regarding the risks and benefits of antibiotic prophylaxis.

Once the decision for antibiotic prophylaxis has been made, the keys to successful prevention are proper timing and administration of the antibiotic and the proper choice of antibiotic for the particular procedure. Since the pivotal study by Classen and colleagues, particular emphasis has been placed on the timing of prophylaxis to be given within 2 hours of incision (Classen et al, 1992). This emphasis was exemplified by the Joint Commission's Surgical Care Improvement Project (SCIP) guideline for administration of antibiotic prophylaxis 60 minutes before incision in a broader effort to decrease overall surgical complications by 25% by 2010. A multi-institutional trial involving more than 4400 patients at 29 institutions reported results of their analysis on the optimal timing of antibiotic prophylaxis (Steinberg et al, 2009). The results suggested an improvement in prevention of SSI when antibiotics were administered within 30 minutes of incision as compared with 31 to 60 minutes (adjusted odds ratio [OR] 1.48, $P = .06$). More important, this larger study confirmed the significantly increased risk of SSI when antibiotics were administered at the time of or following incision, with an adjusted OR of 2.20, $P = .02$. The duration of antibiotic prophylaxis is more controversial; however, most recommendations advocate no more than 24 hours in a patient without an established infection. Routine antibiotic use beyond 24 hours increases the risk of *Clostridium difficile* colitis, increases the development of antibiotic resistance, and increases costs. Along with timing and duration, proper administration of

BOX 5-3 Surgical Wound Classification

CLEAN

- Uninfected wound without inflammation or entry into the genital, urinary, or alimentary tract
- Primary wound closure, closed drainage

CLEAN CONTAMINATED

- Uninfected wound with controlled entry into the genital, urinary, or alimentary tract
- Primary wound closure, closed drainage

CONTAMINATED

- Uninfected wound with major break in sterile technique (gross spillage from gastrointestinal tract or nonpurulent inflammation)
- Open fresh accidental wounds

DIRTY INFECTED

- Wound with preexisting clinical infection or perforated viscera
- Old traumatic wounds with devitalized tissue

Data from Garner JS. CDC guideline for prevention of surgical wound infections, 1985. Supersedes guideline for prevention of surgical wound infections published in 1982. antibiotics implies proper dosage. Antibiotic dose is dependent on the patient's body weight, renal function and hepatic function, and duration of procedure (readministration is required if longer than 4 hours). The second key to successful prevention is the proper choice of antibiotic for the procedure in question. As mentioned earlier, surgery-specific factors affect the type of pathogen, route of entry, and likelihood of systemic infection. For example, the choice of antibiotic is different for transurethral resection of the prostate (TURP; need coverage for common urinary tract pathogens) than for a cystectomy with planned sigmoid colon urinary diversion (need coverage for anaerobic bacteria). Another important consideration is the rate of antibiotic resistance in the community. **Although there is level 1 evidence for the use of fluoroquinolones as prophylaxis for urologic endoscopic procedures, the emerging *Escherichia coli* resistance in the community is changing practice patterns in many practices and high-resistance hospitals.** One resource that is particularly useful is the hospital antibiogram. These reports are published monthly at most major hospitals and quantify the susceptibility and resistance of common organisms to a wide variety of antibiotics. A summary of the recent American Urological Association (AUA) best practice statement on antibiotic prophylaxis

is shown in Table 5-4. In 2012 the AUA issued an amendment to the best practice statement with regard to prostate biopsy, acknowledging the emerging resistance to fluoroquinolones and recommending cephalosporins and/or aminoglycosides in certain communities.

Bowel Preparation

Since antibiotics were first shown to reduce infectious complications in GI surgery, mechanical and antibiotic bowel preparation has been a mainstay of urologic surgery employing intestinal segments. The rationale for bowel preparation before intestinal surgery is to decrease intraluminal feces and decrease bacterial colony counts to decrease the rate of anastomotic leak, intra-abdominal abscesses, and wound infections. The bacterial flora in the bowel consists of aerobic organisms, the most common of which are *E. coli* and *Enterococcus faecalis*, and anaerobic organisms, the most common of which are *Bacteroides* species and *Clostridium* species. **The bacterial concentration ranges from 10 to 10⁵ organisms per gram of fecal content in the jejunum, 10⁵ to 10⁷ in the distal ileum, 10⁶ to 10⁸ in the ascending colon, and 10¹⁰ to 10¹² in the**

descending colon. The preparation itself consists of two components: antibiotic preparation and mechanical preparation. Because there are only a few small series in the urologic literature, the rationale for each must be inferred from the general surgery literature—specifically, from colorectal surgery literature.

Although preoperative parenteral antibiotic prophylaxis before intestinal surgery is well established and widely used, oral antibiotic preparation is still somewhat controversial. Several oral antibiotic regimens are used today. The most commonly used regimen, oral neomycin and erythromycin, first became established with the landmark study by Nichols and Condon in 1977 (Clarke et al, 1977). In a double-blind, placebo-controlled study, 167 patients undergoing elective colonic surgery were randomized to receive mechanical bowel preparation with or without oral neomycin and erythromycin. The overall rates of septic complications were 43% with mechanical-only preparation and 9% with antibiotic plus mechanical preparation ($P = .001$). However, with current standards of the use of preoperative parenteral antibiotics, the benefit of oral antibiotic preparation was debated. Several older studies reported decreased infectious complications; however, these studies were small and there have been no randomized controlled trials (RCTs) to document the benefit. The disadvantage of oral antibiotic preparation is primarily related to increased incidence of pseudomembranous colitis secondary to *C. difficile* infection. In a retrospective analysis of 304 patients, Wren and colleagues reported a significantly decreased incidence of *C. difficile* colitis in patients who did not receive oral antibiotics before elective colorectal surgery (2.6% vs. 7.2%, $P = .03$) (Wren et al, 2005). Inferring from the

colorectal literature, most current guidelines and a 2009 Cochrane review recommend both intravenous and oral antibiotic prophylaxis before elective colorectal surgery (Nelson et al, 2009). Despite the lack of level 1 evidence in the literature, a recent survey of colorectal surgeons revealed that up to 87% of surgeons continue to administer oral antibiotic bowel preparation before elective surgery (Zmora et al, 2003).

Mechanical bowel preparation predates the use of antibiotics in intestinal surgery and was thought to decrease the rate of anastomotic complications. Before the development of nonabsorbable liquids, patients underwent several days of oral laxatives, bowel irrigations via nasogastric tubes, and repeat enemas. These regimens were associated with significant patient discomfort and clinical morbidity caused by electrolyte imbalances. The development of polyethylene glycol solution (GoLYTELY) and sodium phosphate solution (Fleet Phospho-soda) reduced much of the electrolyte disturbance and allowed for mechanical bowel preparation to be done in the outpatient setting. Both regimens are suitable for most patients; however, polyethylene glycol is preferred in the elderly and in patients with renal insufficiency, congestive heart failure, existing electrolyte disturbances, and cirrhosis because it is completely nonabsorbable.

The benefit of mechanical bowel preparation has been assumed for decades as evidenced by 99% positive response by colorectal surgeons when asked if mechanical preparation is routinely used (Zmora et al, 2003). However, RCTs have called into doubt the true benefit. Slim and colleagues published a meta-analysis of RCTs including a total of 4859 patients (Slim et al, 2009). The analysis

included 14 trials including two large trials from the Netherlands and Sweden (Contant et al, 2007; Jung et al, 2007). Overall, the analysis revealed that mechanical bowel preparation provided no benefit for anastomotic leak (OR 1.12, 95% confidence interval [CI] 0.82 to 1.53, $P = .46$); abdominal or pelvic abscess (OR 0.90, 95% CI 0.47 to 1.72, $P = .75$); or mortality (OR 0.91, 95% CI 0.57 to 1.45, $P = .70$). In fact, when overall SSI was considered, mechanical bowel preparation was associated with a significantly increased risk (OR 1.40, 95% CI 1.05 to 1.87, $P = .02$). These results were reiterated in an updated Cochrane review, which found no significant differences in anastomotic leak rate or wound infection, need for reoperation, and mortality rates (Guenaga et al, 2011). The authors concluded that there was no evidence that mechanical bowel preparation improves patient outcome after elective colorectal surgery. Although similar studies have not been done in patients undergoing elective urologic surgery, urologists can make inferences from the colorectal literature and should reevaluate the common practice of mechanical bowel preparation before urologic intestinal surgery. To date there have been multiple single institution reports suggesting equivalent SSI outcomes with or without bowel preparation before radical cystectomy and urinary diversion (Zaid et al, 2013). Two specific exceptions are transrectal ultrasound-guided prostate needle biopsy and laparoscopic urologic surgery. Given the portal of entry and subsequent risk of bacteremia, most urologists have advocated for mechanical rectal cleansing with an enema before transrectal ultrasound-guided prostate needle biopsy. With regard to laparoscopy, surgeons who perform minimally invasive procedures have long believed that preoperative bowel preparation improves operative exposure because of bowel decompression and decreases the incidence of postoperative ileus. However, to date there have been no trials to support this assertion.

In the early postoperative period, most patients experience some degree of primary ileus and delayed GI activity. Any patient with ileus lasting more than 72 to 96 hours after surgery should be evaluated for a mechanical bowel obstruction secondary to adhesions, an intra-abdominal pathologic process, or retroperitoneal hemorrhage. Given that return of GI function is often the rate-limiting factor for hospital discharge, efforts to reduce ileus including minimization of parenteral or oral opioid use, selective use of nasogastric tubes, and correction of electrolyte imbalances should be employed. More recently, methods to accelerate GI recovery have been investigated. Gum chewing—that is, sham feeding—was evaluated and reported to be associated with improvements in GI recovery and reduction in length of stay in patients undergoing colorectal surgery (Ho et al, 2014). Alvimopan (Entereg) is a peripherally acting opioid antagonist that was approved by the U.S. Food and Drug Administration (FDA) in 2008 to help restore bowel function after surgery. With the validation of alvimopan established in the colorectal literature, there have been several studies performed in

patients undergoing cystectomy including a phase 4 trial whose findings were recently published. Use of alvimopan compared with placebo resulted in decreased length of stay of 2.6 days in patients undergoing radical cystectomy (Kauf et al, 2014). Many high-volume centers are now incorporating both strategies into enhanced recovery after surgery (ERAS) clinical pathways to reduce postoperative ileus and reduce hospital stays.

Venous Thromboembolic Prophylaxis

Venous thromboembolic complications are a major cause of potentially preventable morbidity and mortality among surgical patients in the United States. A recent study from the Center for Quality Improvement and Patient Safety and the Agency for Healthcare Research and Quality found postoperative venous thromboembolism (VTE) to be the second most common cause of excess length of stay, charges, and mortality among surgical patients discharged from acute care hospitals (Zhan and Miller, 2003). Urology patients in particular have an increased incidence, estimated to be 10% to 40% in patients without any prophylaxis (Geerts et al, 2008). Although these estimates are based on historical studies conducted before the routine use of mechanical prophylaxis and the recognition of the benefits of early ambulation, the increased risk persists, with more recent studies reporting incidences of 1% to 5%. Urologic patients followed prospectively in the European @RISTOS study developed VTE in 1.9% undergoing open surgery despite a high rate of prophylaxis (Scarpa et al, 2007). For patients in the United Kingdom undergoing urologic procedures, Dyer and colleagues reported an overall incidence of 0.66% including a 2.8% incidence among patients undergoing radical cystectomy (Dyer et al, 2013). Overall, VTE is the most important cause of nonsurgical mortality among urology patients (Forrest et al, 2009).

Although the use of perioperative mechanical prophylaxis (pneumatic compression stockings) is fairly universal, pharmacologic prophylaxis is administered only after weighing the risk of VTE versus risk of perioperative bleeding complications (Table 5-5). Leonardi and colleagues reviewed and analyzed 33 RCTs to assess the incidence of bleeding complications in general surgery patients receiving pharmacologic prophylaxis (Leonardi et al, 2006). Although there was a significantly higher rate of minor complications (injection site bruising and wound hematoma), there was no significant difference in major complications (i.e., GI tract bleeding [0.2%] or retroperitoneal bleeding [$<0.1\%$]). Although these results are applicable in general to urology patients, certain urologic procedures, such as TURP and partial nephrectomy, have a specifically higher rate of bleeding complications. Regarding an individual's risk of VTE, both surgery-related risk factors and patient-related risk factors must be considered. Surgical factors specific to urologic surgery to be weighed include general versus

TABLE 5-5 Mechanical and Pharmacologic Venous Thromboembolism Prophylaxis

PROPHYLAXIS	DOSE	ADVANTAGES	DISADVANTAGES
Pneumatic compression stockings	—	Can be used in patients with high bleeding risk Easily standardized for all patients Studied in multiple patient groups	No standards for size, pressure Individual models not specifically studied Less effective than pharmacologic prophylaxis in high-risk groups
Low-molecular-weight heparin	40 mg SC once daily	Once-daily administration Less risk of heparin-induced thrombocytopenia No blood monitoring necessary	Not reversible High cost Relative contraindication in patients with renal insufficiency
Low-dose unfractionated heparin	5000 U SC q8h	Reversible Can be used safely in patients with renal insufficiency Relatively inexpensive	Needs readministration q8-12h Heparin-induced thrombocytopenia

BOX 5-4 Patient-Related Factors Increasing Risk for Venous Thromboembolism

Surgery
 Trauma (major trauma or lower extremity injury)
 Immobility, lower extremity paresis
 Cancer (active or occult)
 Cancer therapy (hormonal, chemotherapy, angiogenesis inhibitors, radiotherapy)
 Venous compression (tumor, hematoma, arterial abnormality)
 Previous venous thromboembolism
 Increasing age
 Pregnancy and the postpartum period
 Estrogen-containing oral contraceptives or hormone replacement therapy
 Selective estrogen receptor modulators
 Erythropoiesis-stimulating agents
 Acute medical illness
 Inflammatory bowel disease
 Nephrotic syndrome
 Myeloproliferative disorders
 Paroxysmal nocturnal hemoglobinuria
 Obesity
 Central venous catheterization
 Inherited or acquired thrombophilia

Modified from Geerts WH, Bergqvist D, Pineo GF, et al. Prevention of venous thromboembolism: American College of Chest Physicians evidence-based clinical practice guidelines (8th edition). *Chest* 2008;133:381S–453S.

neuraxial anesthesia, supine versus dorsal lithotomy position, abdominal versus pelvic surgery with or without lymphadenectomy, and open versus laparoscopic approach. Patient-related risk factors are listed in [Box 5-4](#), with increasing age, malignancy, history of cancer therapy, and others being fairly common among urology patients. In fact, both the *@RISTOS* study and a recent report on minimally invasive radical prostatectomy confirmed several of these factors as being associated with increased risk of VTE in urologic patients ([Scarpa et al, 2007](#); [Secin et al, 2008](#)). In 2008 the American College of Chest Physicians (ACCP) issued guidelines on the prevention of VTE with a strong recommendation that hospitals develop a formal, active strategy to address VTE prevention. **Although prior recommendations from the ACCP advocated individualized risk assessment models to guide therapy, the current recommendations advocate implementation of group-specific thromboprophylaxis routinely for all patients who belong to each of the major surgical groups (e.g., urologic surgery) ([Geerts et al, 2008](#)).** The AUA has published a best practice statement on the use of VTE prophylaxis in urologic patients ([Forrest et al, 2009](#)). These recommendations combine an individualized risk assessment model with each type of urologic surgery. For example, a high-risk patient (multiple patient risk factors) undergoing low-risk surgery may require pharmacologic prophylaxis, as might a low-risk patient undergoing high-risk surgery. The recommendations are summarized in [Table 5-6](#).

Antithrombotic Therapy

Most urologic patients have medical comorbidities; urologists frequently encounter patients on chronic vitamin K antagonist therapy (e.g., warfarin) or antiplatelet therapy for the management of atrial fibrillation, mechanical heart valves, or coronary artery disease. Perioperative management including interruption of this antithrombotic therapy can be a challenging problem. Unlike VTE pharmacologic prophylaxis, warfarin and antiplatelet

TABLE 5-6 Patient Risk Assessment Model and American Urological Association Best Practice Recommendations

PATIENT RISK STRATIFICATION	
Low risk	Minor surgery in patients younger than 40 yr with no additional risk factors
Moderate risk	Minor surgery in patients with additional risk factors Surgery in patients aged 40–60 yr with no additional risk factors
High risk	Surgery in patients older than 60 yr Surgery in patients aged 40–60 yr with additional risk factors (see Box 5-4)
Highest risk	Surgery in patients with multiple risk factors (e.g., age older than 40 yr, cancer, prior venous thromboembolism)
LEVEL OF RISK	RECOMMENDATIONS
Low risk	No prophylaxis other than early ambulation
Moderate risk	Heparin 5000 units q12h SC starting after surgery or Enoxaparin 40 mg (for CrCl <30 mL/min, use 30 mg) SC daily or Pneumatic compression device if risk of bleeding is high
High risk	Heparin 5000 units q12h SC starting after surgery or Enoxaparin 40 mg (for CrCl <30 mL/min, use 30 mg) SC daily or Pneumatic compression device if risk of bleeding is high
Highest risk	Enoxaparin 40 mg (for CrCl <30 mL/min, use 30 mg) SC daily and adjuvant pneumatic compression device or Heparin 5000 units q8h SC starting after surgery and adjuvant pneumatic compression device

CrCl, creatinine clearance.

therapies have been shown to be associated with significant bleeding complications after surgery. Therefore urologists must carefully consider the risk of interruption of chronic anticoagulation to determine the best course of perioperative management of these medications.

Chronic anticoagulation with warfarin is most frequently encountered in patients with atrial fibrillation, mechanical heart valves, or prior VTE. **The pharmacologic half-life of warfarin is 36 to 42 hours, and therefore most guidelines recommend cessation of therapy 5 days before surgery to ensure an INR less than 1.5.** Recently, several new oral anticoagulants (e.g., apixaban, dabigatran, and rivaroxaban), have been introduced to improve efficacy, decrease patient variability, and improve patient convenience. Each of the new medications has different pharmacologic properties, and therefore it is imperative for the surgeon to be familiar with these medications to properly advise the patient ([Douketis, 2010](#)). The larger issue is whether patients require a bridge with short-term anticoagulation between the time of subtherapeutic INR and

TABLE 5-7 Risk Stratification for Arterial or Venous Thromboembolism Events during Perioperative Period in Patients on Chronic Anticoagulant Therapy

INDICATIONS FOR ANTICOAGULANT THERAPY			
	MECHANICAL HEART VALVE	ATRIAL FIBRILLATION	RECENT VTE
Low	Bileaflet aortic valve prosthesis without atrial fibrillation and no other risk factors for stroke	CHADS ₂ score of 0-2 (and no prior stroke or transient ischemic attack)	Single VTE occurred >12 mo ago and no other risk factors
Moderate*	Bileaflet aortic valve prosthesis plus one of the following: atrial fibrillation, prior stroke or transient ischemic attack, hypertension, diabetes, congestive heart failure, age above 75 yr	CHADS ₂ score of 3-4	VTE within the past 3-12 mo Nonsevere thrombophilic conditions (e.g., heterozygous factor V Leiden mutation, heterozygous factor II mutation) Recurrent VTE Active cancer (treated within 6 mo or palliative)
High*	Any mitral valve prosthesis Recent (within 6 mo) stroke or transient ischemic attack	CHADS ₂ score of 5 or 6 Recent (within 3 mo) stroke or transient ischemic attack Rheumatic valvular heart disease	Recent (within 3 mo) VTE Severe thrombophilia (e.g., deficiency of protein C, protein S, or antithrombin; presence of antiphospholipid antibodies; multiple abnormalities)

*Patients at moderate or high risk are recommended to undergo bridging anticoagulation with therapeutic-dose subcutaneous low-molecular-weight heparin or intravenous unfractionated heparin.

CHADS₂, congestive heart failure–hypertension–age–diabetes–stroke; VTE, venous thromboembolism.

Modified from Douketis JD, Berger PB, Dunn AS, et al. The perioperative management of antithrombotic therapy: American College of Chest Physicians evidence-based clinical practice guidelines (8th edition). Chest 2008;133:299S–339S.

surgery. The decision is based on risk of a thrombotic event. Regarding atrial fibrillation, clinical scoring systems such as congestive heart failure–hypertension–age–diabetes–stroke (CHADS₂), stratify patients into risk groups that predict risk of stroke while patients are not undergoing anticoagulation therapy. Patients with mechanical heart valves can also be stratified into risk groups according to the location (mitral versus aortic) and type of valve used. Similarly, patients with a prior history of VTE are stratified according to duration since last VTE and the patient's risk of recurrent VTE (Table 5-7). In general, the ACCP, which released its guidelines in 2008, recommends that patients in the moderate- and high-risk groups undergo bridging anticoagulation with therapeutic-dose subcutaneous low-molecular-weight heparin or intravenous unfractionated heparin (Douketis et al, 2008).

An increasing number of patients are receiving chronic antiplatelet therapy in the prevention of cardiovascular events and, more important, in the prevention of coronary stent thrombosis. Although the former indication poses little controversy for the urologist, the latter indication presents a significant and complex clinical question in which the urologist must weigh the risk of bleeding with the potentially devastating risk of perioperative stent thrombosis. Aspirin and clopidogrel are the two most commonly used antiplatelet drugs and are frequently used together. Both are irreversible inhibitors of platelet function and therefore need to be stopped 7 to 10 days before surgery to minimize bleeding risk. Current recommendations require dual antiplatelet therapy for 6 weeks after bare metal coronary stents and 12 months for drug-eluting stents. Premature interruption of antiplatelet therapy has been associated with a 25% to 50% risk of significant myocardial infarction with resultant increased perioperative mortality (O'Riordan et al, 2009). In most patients, urologists should defer elective surgery until after antiplatelet therapy can be safely interrupted. In a review of the literature, Gupta and colleagues recommend delay of elective urologic surgery for at least 30 days for bare metal stents and, if possible, longer than 1 year for drug-eluting stents (Gupta et al, 2012). Even then, because acute stent thrombosis has been described with drug-eluting stents after 12 months, urologists should strongly consider at least single-agent antiplatelet therapy in these patients. Given the current lack of

clinically useful alternatives to antiplatelet therapy, when surgery cannot be delayed (e.g., because of malignancy), the ACCP strongly recommends continuing aspirin and clopidogrel during the perioperative period in patients with drug-eluting stents (Douketis et al, 2012). Obviously, communication between the urologist and the cardiologist throughout the perioperative period is essential to minimize complications.

ANESTHETIC CONSIDERATIONS

The basic tenet of anesthesia is to deliver hypnosis, amnesia, and analgesia while maintaining satisfactory operating conditions. An understanding of the basic pharmacologic principles, anesthetic equipment and monitoring, and patient analgesia is important to any surgeon including the urologist for successful operative outcomes and avoidance of surgical complications. Although urologists are performing increasingly more procedures in the office, the bulk of urologic surgery occurs in the operating room under monitored anesthesia care, regional anesthesia, or general anesthesia. Current practice in operative anesthesia employs a combination of inhalational agents and intravenous medications along with analgesics (for pain control) and benzodiazepines (for anxiolysis and amnesia). Of course, improved presurgical evaluation, pharmacologic drugs, and perioperative monitoring have dramatically decreased the risks of anesthesia. A recent study of New York hospital-based and freestanding ambulatory surgical centers reported the risk of all-cause mortality to be 1 in 49,012 and the rate of immediate admission to an inpatient facility to be 0.6% (Fleisher et al, 2007b).

Selection of Mode of Anesthesia

An important role of the urologist in the anesthetic evaluation is to determine what mode of anesthesia is best for the particular patient and surgical procedure. The choice depends on patient-related factors including comorbidities, airway, and patient preference and procedural factors including complexity, duration, anatomic location, and expected fluid and blood loss. A basic

understanding of each method of anesthesia and the pharmacologic principles will aid the urologist in making recommendations to the anesthesiologist.

Monitored Anesthesia Care

Although *monitored anesthesia care* is defined as conscious sedation under the care of an anesthesiologist in a monitored situation, it encompasses a wide range of levels of anesthesia from minimal sedation to brief intervals of unconscious general anesthesia. Most commonly, anesthesiologists combine intravenous opioid analgesics and benzodiazepines to maintain a sufficient level of patient comfort and anxiolysis. Monitored anesthesia care is widely used in urology in the ambulatory setting and is suitable for short-duration endoscopic procedures, transrectal ultrasound-based procedures, and, when combined with a local anesthetic, superficial procedures of the external genitalia. Conscious sedation can be administered in the office setting but only with proper monitoring of the patient during and after the procedure. **The Joint Commission has strict guidelines to ensure that the patients receive the same level of monitoring as if under the care of an anesthesiologist including a requirement for a trained monitoring assistant, immediate access to airway and resuscitation equipment, and specific preprocedure and postprocedure evaluations.**

Regional Anesthesia

Regional anesthesia incorporates different levels of anesthesia directed toward the surgical site, including local anesthesia, spinal anesthesia, and epidural anesthesia. The use of local anesthetics is typically combined with monitored anesthesia care for superficial procedures in an isolated anatomic location. The keys to proper local anesthetic administration are avoidance of intravascular injection and knowledge of pharmacology. The two most commonly used drugs are lidocaine and bupivacaine, with the primary differences being the onset and duration of action. Infiltration of local anesthetics before surgical incision decreases nociceptor sensitization and conduction and results in decreased postoperative pain and analgesic requirements.

Spinal and epidural anesthesia involves injection of anesthetic (most commonly lidocaine or bupivacaine) into the subarachnoid space or epidural space with direct effect on the spinal cord, resulting in sensory, motor, and sympathetic blockade. In urologic procedures, epidural anesthesia is most useful for postoperative pain management for major abdominal procedures, thereby avoiding the adverse effects of high doses of intravenous opioids (i.e., respiratory depression, GI dysfunction). Spinal anesthesia is suitable for most urologic endoscopic procedures and lower abdominal surgical procedures and is limited only by the duration of anesthesia required. Spinal anesthesia avoids the cardiopulmonary effects and complications of general anesthesia. Several factors affect the spinal level and efficacy of administration. In general, larger volume and increased doses result in longer duration and increased cephalad migration. The addition of low-dose opioids and/or vasoconstrictors prolongs the duration of analgesia while reducing the dose of anesthetic. The anesthetic-related adverse effect is hypotension as a result of sympathetic blockade and occurs in 10% to 40% of patients (Di Cianni et al, 2008). **The primary technique-related complication is post-dural puncture headache (results from cerebrospinal fluid leak) with an incidence of less than 2% with currently used 29-gauge pencil-tipped needles (Turnbull and Shepherd, 2003).** Overall, spinal anesthesia has become safe, with the incidence of serious neurologic deficits being 0.05%.

General Anesthesia

Inhalational General Anesthesia. Inhalational drug development has emphasized inhalational agents that facilitate rapid induction and emergence and are nontoxic. Two of the most important characteristics of inhalational anesthetics are the blood/gas solubility coefficient (B/G) and the minimum alveolar

concentration (MAC). The B/G refers to the serum uptake of the inhaled agent, and the MAC is a measure of the potency of a volatile anesthetic (i.e., the serum level required to prevent movement in response to a skin incision in 50% of patients). The various inhalational agents differ not only in the B/G and MAC but also in their cardiopulmonary effects. Obviously, a basic understanding of these properties is important for the urologic surgeon, especially during instances of surgical complication.

Nitrous oxide (NO) is one of the most commonly used agents because of its propensity for rapid induction and emergence; however, because of its low potency, it is often combined with other agents. Because of NO's high B/G and tendency to increase the volume and pressure of closed spaces, its use is contraindicated in certain clinical situations such as small bowel obstruction and pneumothorax. During laparoscopic abdominal procedures, surgeons often prefer to avoid the use of NO because of resultant bowel distention and subsequent interference in the operative field. Although this effect is debated in the surgical literature, El-Galley and colleagues reported significantly increased bowel distention and surgical interference with NO use in patients undergoing laparoscopic donor nephrectomy (El-Galley et al, 2007).

Once introduced in the 1950s, halothane rapidly became one of the most commonly used anesthetic agents because of its high potency. However, halothane has several important risks that have since limited its use. It has significant cardiac effects and can precipitate failure in patients with left ventricular dysfunction. Furthermore, it sensitizes the myocardium to the effects of catecholamines (relevant for local anesthetics injected into the surgical site). Finally, there is a 1 in 35,000 incidence of fulminant hepatitis, which can be lethal as a result of overaccumulation of toxic metabolites. More recent advancements in inhalational agents have focused on reduction in toxicity while maintaining the potency and rapidity of halothane. Three of the most commonly used current agents are isoflurane, sevoflurane, and desflurane. Isoflurane, less expensive than the other agents because of the availability of generic equivalents, is widely used as a result of its low cardiac depression, lower myocardial sensitization to catecholamines, and minimal metabolism. The primary unique toxicity is variable response tachycardia, which can lead to significantly increased myocardial oxygen consumption. Unlike isoflurane, which has a putrid odor, sevoflurane is often used for inhalation induction (odorless) because of its rapid induction and emergence, decreased incidence of postoperative nausea (important in outpatient surgery), and minimal cardiac toxicity. It is, in general, the preferred agent for difficult airways requiring mask induction and in patients with severe bronchospastic disease. Desflurane, like isoflurane, has a pungent odor and is not used for inhalational induction. Its primary advantage over isoflurane is a more rapid recovery in patients requiring anesthesia over 3 hours.

Intravenous General Anesthesia. Intravenous anesthesia consists of a combination of induction agent, opioid, and neuromuscular relaxant. Anesthesiologists often prefer intravenous induction with a combination of inhalational and intravenous agents for maintenance of anesthesia. Intravenous induction offers several advantages in that it is rapid, minimizes patient discomfort, and is preferred by children and most adults. Thiopental, the oldest and least expensive agent, is a suitable choice for uncomplicated situations but is limited in more complex cases because of its significant vasodilation, cardiac depression, and risk of bronchospasm, especially in patients with reactive airway disease. Ketamine is a preferred choice for procedures that are brief and superficial because of its profound amnesia and somatic analgesia. It is associated with increased arteriolar and bronchomotor tone and is advantageous during induction for hypovolemic and asthmatic patients. Propofol is among the most commonly used anesthetic agents, especially in outpatient surgery. It has a rapid onset, produces excellent bronchodilation in patients with reactive airway disease, and, perhaps most important, is associated with smooth, nausea-free emergence from anesthesia. Its primary adverse effect is significant blood pressure reduction. Midazolam, never used as a single agent, produces profound amnesia and anxiolysis while

having a rapid onset and short duration and producing minimal cardiac side effects.

Although these agents induce unconsciousness and amnesia, opioids have become an integral component to all forms of anesthesia. Opioids result in significant analgesia without an increase in cardiac side effects. Several studies have documented the decreased requirements of other agents when used in combination with opioids, thus reducing the overall cardiopulmonary side effects of anesthesia (Fukuda, 2009). Opioids themselves are differentiated in their potency, onset of action, duration of action, and metabolism and excretion. **Fentanyl (synthetic opioid) is probably the most widely used because of its potency (100 to 150 times that of morphine), rapid onset, and short duration of action.** Newer synthetics are geared toward shorter duration and more rapid metabolism.

For major operative cases, complete neuromuscular relaxation is required for sufficient exposure and successful outcome. Although full relaxation can be achieved with intravenous and inhalational agents, the dose required is extremely high. The use of intravenous neuromuscular blockers allows for neuromuscular relaxation and minimization of inhalational and intravenous drugs. **There are two types of neuromuscular blockers: depolarizing drugs, which depolarize the plasma membrane of skeletal muscle fibers, making the fibers resistant to further stimulation by acetylcholine; and nondepolarizing drugs, which block the binding of acetylcholine to cholinergic receptors on the presynaptic and postsynaptic membrane.** Succinylcholine, the only depolarizing drug on the market, is chosen for its rapid onset (used in rapid induction sequences), relatively short duration (around 5 minutes), and rapid metabolism. Its use is limited because of the risk of malignant hyperthermia (when used in combination with volatile inhalational agents), hyperkalemia, and bradycardia in children. When succinylcholine is contraindicated, nondepolarizing agents are used. Several nondepolarizing drugs are available and differ in routes of metabolism and adverse effects. Furthermore, multiple medications including desflurane can alter the metabolism of these drugs and potentiate their actions. The most important consideration in the use of neuromuscular blockers is the assessment of adequate return of neuromuscular function after withdrawal of the drug. The most common complication of neuromuscular-blocking drugs is inadequate reversal resulting in respiratory failure and reintubation. Numerous reports in the literature correlate residual neuromuscular blockade with increased postoperative pulmonary complications in the postanesthesia care unit (PACU) and in the postoperative period. **The concept of train-of-four fade ratio (TOF) was developed to devise an objective measure of adequate neuromuscular function.** This concept refers to the magnitude of the fourth of four twitches in response to maximal stimuli to the ulnar nerve delivered at 0.5-second intervals. Historically, a TOF of 0.7 (meaning that the fourth twitch was 70% the magnitude of the first twitch) correlated with adequate return of neuromuscular function; however, more recent standards have raised the threshold to 0.9 as an indicator of complete return of neuromuscular function (Kopman et al, 1997). Currently, anesthesiologists use several clinical assessments including head lift, tongue depressor test, and hand grip to estimate a TOF of 0.9. A recent study revealed that with use of clinical assessments alone, 16% and 45% of patients 2 hours after a single intubating dose of neuromuscular blocker had a TOF of less than 0.7 and less than 0.9, respectively, in the PACU (Debaene et al, 2003). As such, current recommendations are that quantitative TOF measurement (acceleromyography) be combined with clinical assessments before extubation in the operating room (Viby-Mogensen, 2009).

Pain Management

Equally important to intraoperative anesthetic considerations, proper pain management after surgery is crucial to minimizing postoperative complications and delayed recovery. **Untreated acute pain not only is unacceptable for the patient, but also may increase the risk of complications by causing increased**

physiologic stress in the recovery period. The neural process, referred to as *nociception*, involves signal transduction from noxious stimuli via sensory afferent nerves to the spinal cord and cerebral cortex, resulting in the perception of pain. Analgesia aims to block the pain sensation along various points of this signal transduction pathway.

Opioids are perhaps the most commonly used analgesic medications in the immediate postoperative period. These drugs primarily act in the CNS at both the dorsal root ganglion and the cerebral cortex to modulate the perception of pain. Administration can be oral, intravenous, neuraxial, or transdermal. In general, the choice of route of administration is dependent on patient's severity of pain and ability to take oral medications. Although typically very effective for providing analgesia, opioids can cause decreased GI activity, respiratory suppression, sedation, and mental confusion. Weaker (less potent) opioids, such as hydrocodone and codeine, may minimize these adverse effects but are often combined with acetaminophen and should be used with caution in patients with hepatic insufficiency.

Nonsteroidal anti-inflammatory drugs (NSAIDs) are being employed in the postoperative setting more frequently now to avoid the unwanted effects of opioids. These medications act by inhibition of cyclooxygenase enzyme activity, resulting in decreased prostaglandin production. Prostaglandins are the primary mediators of nociceptor activation at the tissue level. **Multiple studies have demonstrated that the appropriate use of NSAIDs can result in decreased use of opioid analgesics and decreased nausea and vomiting after anesthesia** (Rawlinson et al, 2012). In a randomized study of patients undergoing laparoscopic colon surgery, the use of intravenous ketorolac was associated with improved pain scores and reduced postoperative ileus (Schlachta et al, 2007). NSAIDs are usually very well tolerated but should be avoided in patients with renal insufficiency and used with caution in patients with a history of esophageal reflux or peptic ulcer disease.

For major abdominal surgery in which prolonged opioid use is expected, neuraxial analgesia (i.e., epidural) can provide significant patient benefits. Epidural analgesia is administered and monitored by the anesthesia or pain management team. Both opioids and local anesthetic medications are infused in the epidural space via catheter and are given as a continuous infusion and/or patient-controlled infusion. Epidural analgesia has the advantage of improved pain control while minimizing the central nervous and GI adverse effects of intravenous opioid medications. Block and colleagues performed a meta-analysis of randomized trials to review the efficacy and concluded that epidural analgesia, regardless of agent or location of catheter placement, provided better pain control than parenteral opioids (Block et al, 2003). In fact, a recent review of RCTs found that in patients undergoing general anesthesia, the use of concomitant epidural analgesia resulted in decreased perioperative mortality and improved comorbidity end points across multiple organ systems (Pöpping et al, 2014).

BLOOD PRODUCTS

Given the vascular nature of urologic organs, the urologist often confronts the issue of indication and necessity of transfusion in the perioperative period. Therefore it is important that the urologist understand the indications, implications, and risks associated with blood product transfusion. Before the acquired immunodeficiency syndrome (AIDS) epidemic, blood transfusion was liberally administered, often for any patient with a hematocrit less than 30%. However, fear and concern about the infectious risk led to the convening of a National Institutes of Health (NIH) panel to develop consensus recommendations for the indication of blood product transfusion (NIH Consensus Statement, 1988). The principles in these guidelines largely hold true today as reflected by the ASA practice guidelines issued in 2006 (*Practice guidelines for perioperative blood transfusion and adjuvant therapies*, 2006). To summarize, the guidelines indicate that transfusion is rarely indicated with hematocrit greater than 30% and often indicated

for hematocrit less than 21%. For levels between 21% and 30%, clinical factors such as risk of complications from inadequate oxygenation should guide the need for transfusion, balancing the risks and benefits. In general, patients with relatively minor comorbidities can tolerate hematocrit of greater than 21% before transfusion is indicated. Patients with moderate to severe comorbidity (e.g., significant pulmonary compromise, coronary artery disease, or vascular insufficiency, or with signs or symptoms of hypovolemic, hemorrhagic shock) warrant transfusion to achieve hematocrit greater than 30%. Ultimately, until technology is available to directly measure inadequate oxygen-carrying capacity, the urologist should individualize the decision to transfuse for each patient and clinical situation.

A major advance in blood banking and product transfusion has been the development of component therapy allowing for administration for specific fractions of whole blood. Packed red blood cells (PRBCs) are equivalent to whole blood minus the plasma component. Whereas the hematocrit in whole blood is 40%, it is 70% in PRBC units. These units are reconstituted and administered with crystalloid. Given the lack of the remaining components, in instances of massive PRBC transfusions and associated bleeding, platelets and occasionally fresh frozen plasma (FFP) should be given to avoid dilutional coagulopathy. Platelet transfusion is rarely indicated empirically except in patients with significant thrombocytopenia ($<50,000/\text{mm}^3$) and a planned surgical procedure or with moderate thrombocytopenia (50,000 to $100,000/\text{mm}^3$) and either a high-risk procedure or evidence of platelet dysfunction. Similarly, empirical transfusion with FFP for massive transfusion is not indicated. With the development of component therapy, the use of FFP increased dramatically, leading to consensus statements from the NIH and the ASA to guide practitioners ([Consensus conference, 1985](#); [Practice guidelines for perioperative blood transfusion and adjuvant therapies, 2006](#)). The current indications for FFP transfusion are immediate reversal of warfarin-induced coagulopathy, replacement in patients with specific clotting factor deficiencies, and evidence of bleeding and INR greater than 1.5. According to the ASA guidelines, in patients with massive transfusion and no INR readily available, FFP should be given after replacement of 1 blood volume.

There are well-documented risks of transfusion, and these risks should always be discussed with the patient before administration. Hemolytic transfusion reactions occur as a result of incompatibility between donor and recipient (either ABO or non-ABO incompatibility). According to the 2007 FDA Annual Summary, from 2005 to 2007 transfusion reactions accounted for 22% of transfusion-related fatalities in the United States ([U.S. Food and Drug Administration, 2007](#)). Transfusion reactions occur relatively frequently and, if identified early, can be treated with rare catastrophic events. The early signs and symptoms include fever, chills, chest pain, hypotension, and bleeding diathesis occurring during or immediately after transfusion. Reactions may also occur in a delayed fashion, which is characterized by significant intravascular hemolysis secondary to recipient antibodies. The treatment of transfusion reaction is centered on fluid resuscitation, cessation of the transfusion, and alkalization of the urine to prevent renal failure. **The most common cause of transfusion-related fatality is transfusion-related acute lung injury (TRALI). This entity accounted for 55% of transfusion mortality from 2005-2007. The injury is characterized by noncardiogenic pulmonary edema injury and manifests 1 to 2 hours after transfusion. Although no specific treatment other than supportive measures is indicated, most patients recover without significant sequelae. Finally, one of the most feared complications (at least in the public eye) is the transmission of bacterial or viral infection. Although the risk of hepatitis virus and human immunodeficiency virus (HIV) transmission was unacceptably high in the 1970s and 1980s, the initiation of more stringent screening procedures for high-risk populations and the development of nucleic acid amplification technology (polymerase chain reaction [PCR] and transcription-mediated amplification) have resulted in dramatically reduced risk and incidence of viral transmission. Currently, the risk of HIV and hepatitis C transmission is approximately 1 in 2**

million cases, whereas the risk of hepatitis B transmission is 1 in 200,000. The highest risk of infectivity occurs with platelet transfusion, in which bacterial contamination develops at a rate of 1 in 5000 units ([Eder et al, 2007](#)).

Although very high-blood loss procedures in urology are uncommon, given the proximity of major vascular structures to several genitourinary organs, occasionally the urologist is faced with a clinical situation in which a large-volume blood transfusion is necessary. Traditionally, component transfusion would not begin until more than 6 units of PRBCs had been given to the patient. More recently, evidence from the trauma literature supports the use of an increased ratio of platelets to fresh frozen plasma to red blood cells (RBCs)—that is, massive transfusion protocol. The protocol is triggered in the anticipation of greater than 10 units of PRBCs per 24 hours and mobilizes blood bank and hospital resources to provide an adequate supply of RBC and component transfusion. There are multiple reports of improved survival of trauma patients managed with massive transfusion protocols. A study from Ball and colleagues demonstrated improved abdominal wall closure rates among patients with high-grade liver injuries when a massive transfusion protocol was used ([Ball et al, 2013](#)).

PATIENT ENVIRONMENT

Patient Temperature

Although hypothermia can be therapeutic in certain situations of trauma and brain injury, for elective surgical procedures, hypothermia is associated with significantly increased morbidity to the patient. There are two primary reasons for hypothermia to develop in the operating room. Anesthetic agents induce peripheral vasodilation, redistributing heat from the core (trunk, head) with a resultant drop in immediate core temperature after induction. Throughout the rest of the surgical procedure, radiation and conductive heat loss account for most of the heat loss. Normothermia is defined as a core temperature between 36°C and 38°C , and hypothermia of even 1°C to 2°C results in adverse effects. Rajagopalan and colleagues performed a meta-analysis of RCTs and reported that mild hypothermia (decrease of 1°C) resulted in a 16% increase in estimated blood loss and 22% increase in transfusion requirements ([Rajagopalan et al, 2008](#)). The increased bleeding risk is thought to result from a hypothermia-associated decrease in clotting cascade enzymatic function and platelet aggregation. Even more significant is the increase in the risk of SSIs associated with mild hypothermia (34°C to 36°C). Hypothermia increases the risk of SSI by impairing immune mechanisms and vasoconstriction, resulting in regional tissue hypoxia. In a landmark study, Kurz and colleagues with the Study of Wound Infection and Temperature Group tested in 200 patients undergoing elective colorectal surgery the hypothesis that hypothermia increases the rate of wound infection and hospital stay ([Kurz et al, 1996](#)). **Hypothermia was associated with a three times increased risk of wound infection and a 2.6-day increase in hospitalization.** More recent studies have confirmed these findings in general in other series of surgical patients ([Mauermann and Nemergut, 2006](#)). In its overall goal of reducing SSI, the SCIP has also included perioperative normothermia as one of its guidelines. Strategies to improve maintenance of normothermia include regular use of warming blankets, warmed intravenous fluids, warmed irrigation fluids (especially during TURP and other prolonged endoscopic procedures), warmed humidified CO_2 gas during laparoscopy, and increase in ambient operating room temperature. Although there have been few studies in the urologic literature, the findings can be generalized to all surgical patients.

Skin Preparation

Sterile skin preparation is fundamental in the prevention of SSI for any procedure. Currently the most commonly used skin antiseptics are alcohol, povidone-iodine, or chlorhexidine based. Whichever antiseptic is chosen, the solution should be applied in concentric

circles from the center of the surgical site and allowed to dry before incision. The Cochrane Wound Study group recently published their updated second analysis on various preoperative skin preparations. The authors again were unable to report conclusive evidence of superior efficacy of one particular skin preparation (Dumville et al, 2013). Furthermore, although the CDC clearly recommends preoperative showering or bathing to reduce SSI, there is no evidence that bathing with an antiseptic solution reduces the rate of infection (Webster and Osborne, 2007). Regarding hair removal, the CDC recommends that if hair removal is performed, it should be performed immediately before the surgical procedure and performed with clippers (rather than shaving) (Mangram et al, 1999).

Patient Safety

In 1991 Brennan and colleagues published their seminal work describing adverse events, defined as injuries caused by medical management in hospitalized patients, revealing that 48% of the events accompanied a surgical operation (Brennan et al, 1991; Leape et al, 1991). This important study inspired the publication of "To Err Is Human: Building a Safer Health System," a comprehensive study by the Institute of Medicine on medical errors. Regarding surgical patients, the most frequent venue of preventable injuries is the operating room. **Although the surgeon is the "captain of the ship" and ultimately responsible, it takes cognizance and attention to detail from each member of the operating room team to prevent iatrogenic injuries to the patient.** Three causes of immediately preventable injuries are retractor-associated injuries, thermal injuries, and patient position-related injuries. There are several reports in the literature documenting an increased rate of neuropathy (especially femoral nerve) after laparotomy with self-retaining retractors versus without self-retaining retractors (Irvin et al, 2004). Careful attention to be certain that the lateral blades do not directly

compress the psoas muscle and only cradle the rectus abdominal muscles will ensure avoidance of femoral neuropathy. Furthermore, periodic reinspection of the retractor blades is also warranted. Many devices used in urologic surgery employ thermal energy for desired effect and therefore can result in thermal injury to the patient. These include Bovie cautery, the argon beam coagulator, bipolar devices, and lasers. In both endoscopic and laparoscopic surgery, high-wattage light sources are used to illuminate the operative field. While it is illuminated, the ends of the light cords can result in burns when in direct contact with the patient (even through draping). These light sources should be turned off at all times when not in use. Special mention is deserved for the morbidly obese patient. The operating room should be equipped with a hydraulic table, extra-long instruments, additional padding, wide venous compression devices, and side extensions to ensure a safe operating room environment for the patient.

Patient Positioning

Although often given only a cursory evaluation, proper patient positioning in the operating room can prevent potentially devastating complications. Ultimately, proper positioning is the shared responsibility of each member of the operating room team. Much of the knowledge and guidelines for avoidance of position-related injury are drawn from the anesthesia literature. In fact, in response to a 1999 study of the ASA Closed Claims Database, which found neuropathy as second-leading cause of liability, the ASA published a practice advisory for the prevention of perioperative peripheral neuropathies (Practice advisory for the prevention of perioperative peripheral neuropathies, 2000). The recommendations are listed in Box 5-5. **Although the exact mechanisms of peripheral neuropathy are not always known, the cause of position-related neuropathy is usually secondary to excessive stretch, prolonged compression, or ischemia.** Given the variety of different patient

BOX 5-5 American Society of Anesthesiologists Task Force Recommendations on the Prevention of Perioperative Peripheral Neuropathies

PREOPERATIVE ASSESSMENT

- When judged appropriate, it is helpful to ascertain that patients can comfortably tolerate the anticipated operative position.

UPPER EXTREMITY POSITIONING

- Arm abduction should be limited to 90 degrees in supine patients; patients who are positioned prone may comfortably tolerate arm abduction greater than 90 degrees.
- Arms should be positioned to decrease pressure on the post-condylar groove of the humerus (ulnar groove). When arms are tucked at the side, a neutral forearm position is recommended. When arms are abducted on armboards, either supination or a neutral forearm position is acceptable.
- Prolonged pressure on the radial nerve in the spiral groove of the humerus should be avoided.
- Extension of the elbow beyond a comfortable range may stretch the median nerve.

LOWER EXTREMITY POSITIONING

- Lithotomy positions that stretch the hamstring muscle group beyond a comfortable range may stretch the sciatic nerve.
- Prolonged pressure on the peroneal nerve at the fibular head should be avoided.
- Neither extension nor flexion of the hip increases the risk of femoral neuropathy.

PROTECTIVE PADDING

- Padded armboards may decrease the risk of upper extremity neuropathy.
- The use of chest rolls in laterally positioned patients may decrease the risk of upper extremity neuropathies.
- Padding at the elbow and at the fibular head may decrease the risk of upper and lower extremity neuropathies, respectively.

EQUIPMENT

- Properly functioning automated blood pressure cuffs on the upper arms do not affect the risk of upper extremity neuropathies.
- Shoulder braces in steep head-down positions may increase the risk of brachial plexus neuropathies.

POSTOPERATIVE ASSESSMENT

- A simple postoperative assessment of extremity nerve function may lead to early recognition of peripheral neuropathies.

DOCUMENTATION

- Charting specific positioning actions during the care of patients may result in improvements of care by (1) helping practitioners focus attention on relevant aspects of patient positioning and (2) providing information that continuous improvement processes can use to effect refinements in patient care.

positions used in urologic surgery, it is critical for the urologist to be an active participant in the positioning of the patient and to understand the potential patient compromise that accompanies each position.

The supine position, used in abdominal, pelvic, and penile procedures, is in general considered the safest patient position. However, several specific issues should be considered. **Excessive upper extremity abduction (>90 degrees) can lead to tension on the brachial plexus, leading to upper extremity neuropathy.** The armboard should be padded to avoid excessive pressure on the ulnar groove and spiral groove of the humerus (radial nerve injury). In cases in which the arms are tucked at the patient's side, care must be taken to avoid excessive pressure on the hand and forearm. Moreover, peripheral intravenous catheter infiltration must be identified quickly because forearm compartment syndrome may develop.

One of the most frequent positions used in urology is the lithotomy position. Improper positioning can lead to transient and occasionally prolonged lower extremity neuropathy. In a retrospective evaluation of more than 190,000 cases from 1957 to 1991 involving the lithotomy position, persistent neuropathy was found in 0.03%; however, the same group in a prospective study of 991 patients reported an incidence of 1.5% (15 patients) with resolution of symptoms by 6 months in all but one patient (Warner et al, 1994, 2000). **The basic principle of position involves manipulation of both lower extremities simultaneously with flexion of the hips at 80 to 100 degrees with 30- to 45-degree abduction.** The legs should be padded to avoid excessive compression against the stirrup. Particular caution should be given to the patient's hands to avoid entrapment within the moving parts of the stirrups.

For most open and laparoscopic upper urothelial tract and renal procedures, the patient is placed in some degree of lateral decubitus position. Proper padding of the patient is important, with appropriate anterior and posterior support to maintain the decubitus position. The most frequent focus of compromise involves positioning of the arms and the potential for brachial plexus injury. The ipsilateral arm should be placed on an elevated arm rest or gel pad, avoiding abduction of more than 90 degrees and excessive stretch on the shoulder. The contralateral arm should be placed on an armboard with ulnar padding. Furthermore, in patients in full flank position, an axillary roll should be placed just caudal to the axilla (not in the axilla) to avoid compression of the contralateral brachial plexus. Finally, after the patient has been positioned and before sterile draping, the operating table should be fully rotated to ensure that the patient is adequately secured in all positions.

Two patient positions used in specific urologic cases deserve attention: the prone position for percutaneous nephroscopy and the full Trendelenburg position for robotic-assisted laparoscopic procedures in the pelvis. In the prone position, special care should be taken to pad the torso, elbows, hips, and legs. The anesthesiologist should ensure that the endotracheal tube and all vascular accesses are properly secured. Coordination of the entire team is required during transfer from the supine position on the stretcher to the prone position on the operating room table. A stretcher should always be available immediately in case of airway compromise and the need for rapid transfer to the supine position. Regarding the full Trendelenburg position for minimally invasive pelvic procedures, the primary issues involve the physiologic changes in respiratory function, cardiovascular function, and increases in central venous and intracranial pressures. Patient positioning should focus on properly padding and securing the patient to the operating table to prevent cephalad sliding. Although fixed shoulder braces will undoubtedly prevent patient movement, these braces should be avoided because of the risk of brachial plexus compression and resultant neuropathy.

ABDOMINAL INCISIONS AND WOUND CLOSURE

Abdominal Incisions

Urologic surgery can encompass a large area of the trunk, and therefore the urologist should be familiar with all type of incisions

of the abdomen. The most commonly used incision in surgery including urology is the midline abdominal incision. This incision can provide access to the entire peritoneum and retroperitoneum. For procedures focused on particular areas of the abdomen, alternative incisions provide more focused exposure with certain benefits. A Pfannenstiel incision (transverse lower abdominal incision) can be used for virtually all pelvic procedures and results in improved cosmesis and possibly decreased pain. For access to the lower third of the ureter, a Gibson incision (i.e., an oblique incision in the lower quadrant) can be used. With a Gibson incision, entry into the retroperitoneum is gained by splitting the external and internal oblique muscles in the direction of its fibers. Access to the upper abdomen and retroperitoneum for renal and adrenal surgery can be gained using various kinds of incisions. An extraperitoneal approach is best performed via a flank incision over the 11th or 12th rib, with or without partial rib removal. An extraperitoneal approach avoids the complications of transperitoneal surgery such as bowel injury, postoperative ileus, and adhesion formation. Transperitoneal access can be obtained via an anterior subcostal incision (two fingerbreadths below the costal margin). This incision provides better access to the midline vascular structures by allowing for complete medial mobilization of the posterior peritoneum. For large or locally advanced (vena cava thrombus) tumors, a thoracoabdominal or chevron incision provides the best exposure in general. A thoracoabdominal approach is preferred for large upper retroperitoneal tumors or tumors with extension into the thoracic cavity (supradiaphragmatic vena cava tumor thrombus). On the other hand, a chevron incision is preferred for access to both the right and left abdomen (e.g., bilateral renal tumors). In summary, proper choice of incision is often critical to successful surgical outcome, especially for complex operative cases.

Wound Healing

Knowledge of the basic principles of wound healing is important to properly assess incision closure and its associated complications. All cutaneous wounds progress stepwise through a series of events toward complete wound repair; in a particular wound, different phases of events may occur simultaneously. **The series of steps can be divided broadly into three stages: reactive phase, proliferative phase, and maturational phase.** The reactive phase occurs immediately with the two primary responses of hemostasis and inflammation. Disruption of vascular membranes results in platelet activation and aggregation, which in turn initiate the inflammatory response. During this stage of wound healing, inflammatory cells including polymorphonuclear cells, macrophages, and lymphocytes migrate into the wound and become activated, leading to cytokine activation and secretion of various growth factors. The second stage, proliferative, results in the formation of granulation tissue. The stage is characterized by proliferation of endothelial cells and fibroblasts leading to angiogenesis and epithelialization, which eventually results in growth of immature blood vessels and deposition of extracellular matrix and early collagen scaffolding. Finally, the maturation stage occurs with further deposition of collagen and wound contraction. **The maturational phase begins approximately 1 week after injury and progresses rapidly over 6 weeks, with increasing wound strength over the next 12 months. The scar regains approximately 3% strength after 1 week, 20% after 3 weeks, and 80% after 3 months (Witte and Barbul, 1997).**

Wound Closure

Along with choice of incision, proper closure is necessary to avoid certain surgical complications including wound infection and fascial dehiscence. In general there are three types of wound closure: primary, secondary, and tertiary (or delayed primary closure). In the vast majority of elective procedures, the urologist should attempt a permanent closure after the operation (primary closure). Secondary closure is reserved for heavily contaminated wounds for which the fascia is closed primarily but the skin and subcutaneous tissues are

allowed to heal via re-epithelialization and contraction. Tertiary closures are reserved for patients with abdominal compartment syndrome or patients requiring re-explorations, in whom temporary closure is initially performed with intention of future permanent closure. Unless the procedure involves heavy contamination, incision closure involves reapproximation of the fascia (in one or multiple layers) and the skin. Choice of suture type by the surgeon depends on preferences of braided versus nonbraided, monofilament versus multifilament, and absorbable versus nonabsorbable. A full description of different suture types and their properties is listed in Table 5-8 (Hochberg et al, 2009). Although the method of fascial closure has been studied extensively, a definitive, superior method is not universally agreed upon. van 't Riet and colleagues performed a meta-analysis of available RCTs (van 't Riet et al, 2002). In all, 6566 patients from 15 studies were included; the primary outcome measure was incidence of incisional hernia. The analysis indicated that between slowly absorbable and nonabsorbable sutures there was no difference in risk of incisional hernia in continuous versus interrupted fascial closures, although nonabsorbable closure was associated with increased wound pain and sinus formation. For rapidly absorbable suture types, continuous fascial closure was significantly associated with increased rate of incisional hernias. Because of the limited number of patients, a definitive conclusion could not be made for interrupted rapidly absorbable suture closure versus continuous slowly nonabsorbable suture closure. The authors, however, concluded that mass closure with slowly absorbable suture in a continuous fashion is the optimal method. To address the limitation found in previous meta-analyses, Seiler and colleagues completed an RCT of 625 patients (Seiler et al, 2009). Patients were randomized to one of three arms: interrupted closure with rapidly absorbable suture or continuous closure with one of two different slowly absorbable sutures. They found no significant difference in incisional hernia (15.9% vs. 8.4% vs.

12.2%, $P = .09$), fascial dehiscence, wound infection, or serious adverse events. In conclusion, although incisions may be closed either with interrupted, rapidly absorbable suture closure or with continuous slowly absorbable suture closure, careful attention should be paid to the technique, given the relatively high incidence of incisional hernia. A subsequent meta-analysis of existing literature again could not find a significant difference between continuous closure with slowly absorbable suture versus interrupted closure with rapidly absorbable suture (Diener et al, 2010).

Perhaps the most frequently encountered complication of abdominal wounds is the SSI. Because of different reporting methods and descriptions in the literature, the National Health Care Safety Network of the CDC published definitions of SSIs with clearly defined, objective criteria (Kirby and Mazuski, 2009). The infections are classified as follows:

- Superficial incisional infection: involves only skin and subcutaneous tissue and occurs within 30 days of surgery
- Deep incisional infection: involves deep soft tissues (muscle or fascial planes) and occurs within 30 days of surgery (or within 1 year if implant is in place)
- Organ or space infection: involves any part of the body that is opened or manipulated during the operative procedure and has purulent drainage from a drain placed in the wound or evidence of infection on radiographic imaging

Specific risk factors predisposing to SSIs were previously listed in Box 5-2. The mainstay of treatment centers on adequate drainage of the infected area. Superficial infections and some deep incisional infections can usually be managed with opening of the skin incision and packing of the wound. Care should be taken to open the incision widely to ensure complete drainage of underlying purulent fluid. The use of oral or intravenous antibiotics is not necessary unless the infection is associated with significant skin cellulitis (erythema extending >2 cm from

TABLE 5-8 Properties of Suture Materials

SUTURE	ORIGIN	TISSUE ABSORPTION	PHYSICAL CONFIGURATION	TENSILE STRENGTH	COMMENTS
Vicryl	Synthetic	Absorbable	Braided	65% 2 wk 40% 4 wk	Slower loss of function and higher knot-breaking strength compared with polyglycolic acid (Dexon).
Dexon	Synthetic	Absorbable	Braided	63% 2 wk 17% 3 wk	Lubricant coating decreases coefficient of friction.
Monocryl	Synthetic	Absorbable	Monofilament	30%–40% 2 wk (dyed) 25% 2 wk (undyed)	Excellent tensile strength allows use of smaller sutures for skin closure.
PDS	Synthetic	Delayed absorbable	Monofilament	74% 2 wk 50% 4 wk 25% 6 wk	No absorption until after 90 days; low reactivity, tends to maintain strength in presence of infection; newer barbed version is knotless.
Maxon	Synthetic	Delayed absorbable	Monofilament	81% 2 wk 59% 4 wk 30% 6 wk	
Chromic gut	Natural	Absorbable	Monofilament	0% 3 wk	Can also be found as plain gut (untreated) for faster absorption.
Nylon	Synthetic	Nonabsorbable	Monofilament	50% 1-2 yr	Very low tissue reactivity.
Prolene	Synthetic	Nonabsorbable	Monofilament	No significant loss over time	High plasticity, extremely smooth surface (requires extra knot throws).
Silk	Natural	Nonabsorbable	Braided	Degraded over time	Braided for easier handling; can be prone to infection.
Mersilene	Synthetic	Nonabsorbable	Braided or monofilament	No significant loss over time	Braided should not be used in infection.

incision edge or systemic signs of toxicity, e.g., fever, sepsis) (Barie and Eachempati, 2005). Once opened, the wound should be allowed to heal by secondary intention. Many deeper incisional infections are too extensive for bedside incision and require operative debridement under anesthesia. It is critical to carefully examine any infected wound for signs of necrotizing infection, most commonly secondary to *Clostridium perfringens*. Signs include drainage of grayish, dishwater-colored fluid, frank necrosis of the fascial layer, and wound crepitus. A necrotizing infection requires immediate return to the operating room for wide debridement and washout. In contrast to incisional infections, deeper organ and space infections may cause no superficial signs at the level of the incision. Rather, patients often show systemic signs of infection, pain, or sepsis; cross-sectional imaging is used to reveal the putative source. Again, the principle of adequate drainage applies, and management involves percutaneous or operative drainage of the abscess fluid. A controversial issue in the prevention of organ and space infections is the routine placement of drainage systems at the time of the initial operative procedure. A wide variety of surgical drains is available. Drains are broadly categorized as open nonsuction, closed nonsuction, and closed suction drains. Open nonsuction drains are employed when accurate quantification of drainage amount is not necessary. These drains are associated with less patient discomfort and are the easiest to remove. Closed drains are chosen if quantification of drainage amounts or characterization of drainage fluid is necessary. The use of suction in closed drain systems is in general preferred if immediate recognition of small amounts of drainage is important (e.g., a drain around a ureterointestinal anastomosis). Although drains continue to be widely used in various urologic procedures, several prospective studies in the general surgical literature have failed to show significant benefit; therefore most experts caution against their routine use (unless strong indication exists) (Barie, 2002).

Perhaps the most dreaded complication of surgical incisions is acute wound failure (or fascial dehiscence). Overall the incidence of fascial dehiscence is 1% to 2%, and the complication usually occurs 1 week after surgery, although it may occur up to 30 days postoperatively. Risk factors for dehiscence include patient-related factors (advanced age, malnutrition, corticosteroid use, obesity, and prior history of radiotherapy); SSI; and technical errors at the time of wound closure. The most common technical errors associated with wound failure are placing the suture too close to the fascial edge, knot slippage, and excessive suture tension. **Multiple studies have investigated the type of closure, and there is no difference in dehiscence risk between interrupted and continuous closures as long as rapidly absorbable sutures are not used with the latter.** Historically, in high-risk patients retention sutures were strongly advocated and widely used as a preventive measure for wound dehiscence. Literature evidence, however, was primarily retrospective, and subsequent prospective trials have failed to show evidence of benefit (Carlson, 1997). One recent trial by Rink and colleagues randomized 95 high-risk patients to retention sutures versus standard closure; the researchers reported that although no difference in wound failure rates was seen, retention sutures were associated with a significantly increased rate of patient morbidity, primarily pain (Rink et al, 2000). Accordingly, recent surgical trends suggest a movement away from the use of retention sutures and, alternatively, toward the increased use of grafts and synthetic mesh in wounds thought to be at increased risk of fascial dehiscence. **When acute wound failure does occur, it is usually immediately preceded by a sudden gush of serosanguineous fluid from the wound.** Some small fascial disruptions can be managed conservatively with wound packing and close observation, but the majority of disruptions, particularly in the setting of bowel evisceration, mandate urgent return to the operating room. At the bedside, a sterile, saline-moistened towel should be placed over the eviscerated components while the patient is being prepared for the operating room. At the time of reoperation, the fascial edges are inspected for the cause of the disruption. In cases of technical errors or fascial tearing in which the fascial edges are healthy and can be brought together without tension, a primary closure is

appropriate. In all other cases, the fascial edges are debrided and the wound is closed with absorbable mesh or biologic prosthetic grafts. A full discussion of the different materials is beyond the scope of this chapter, but strong consideration should be given to an intraoperative general surgical consultation.

Whether because of a deep abdominal infection or an acute wound failure, the urologist is often faced with decisions regarding temporary versus permanent closure and primary versus secondary permanent abdominal wall closure. In general, a temporary abdominal closure is considered in situations of significant deep abdominal infection (e.g., bacterial peritonitis secondary to bowel anastomosis breakdown, ischemic bowel) or significant abdominal wall failure (e.g., necrotizing fasciitis). **Perhaps the biggest recent advance in temporary abdominal wall closure was the development of the negative-pressure vacuum pack.** This technique allows safe, inexpensive temporary closure, facilitates wound healing by reducing chronic bowel edema and improving local blood flow, and can result in relatively high delayed primary abdominal wall closure rates. To determine the effectiveness of temporary closure, Bhangu and colleagues performed a meta-analysis of the existing literature on whether temporary closure of contaminated abdominal wounds reduces the rate of deep SSI (Bhangu et al, 2013). **Although the currently available literature is not substantial, they concluded that delayed primary closure of the abdomen was a reliable and potentially cost-saving method to prevent SSI in contaminated wounds.** When delayed primary fascial closure is not feasible, newer biologic prosthetic mesh can be used to close the abdomen and the remaining wound can close secondarily (in conjunction with use of a negative-pressure vacuum-assisted device). These mesh prosthetics are derived from human, porcine, or bovine sources and in general are synthesized at acellular collagen matrices. Although the long-term durability of these materials is not known, they are usually safer in contaminated wounds.

KEY POINTS

- Proper preoperative evaluation of the patient will prevent unanticipated cancellations and decrease the risk of postoperative complications.
- The indications for preoperative cardiac testing depend on three groups of factors: the functional capacity of the patient, cardiac risk factors, and surgery-specific risk factors.
- SSIs are one of the leading causes of perioperative complications and increased hospital stay. Antibiotic prophylaxis is indicated in virtually all surgical procedures.
- VTE is a common complication of urologic procedures, and the AUA recommends either mechanical or pharmacologic prophylaxis (or both for patients at highest risk) for all urologic procedures.
- Proper understanding of the pharmacologic principles of anesthesia will allow the urologist to actively participate in the decision process of choosing which mode of anesthesia will be appropriate for a particular patient and procedure.
- Current guidelines advocate blood product transfusion for hematocrit less than 21% in most patients unless there are specific cardiopulmonary risk factors.
- Perioperative hypothermia of even 1° C to 2° C is associated with increased estimated blood loss and increased risk of SSI.
- Proper choice of surgical incision results in optimal surgical exposure and therefore improved outcomes.
- Current literature suggests that closure with continuous, slowly absorbing suture results in the lowest risk of incision-related complications.

Lower Urinary Tract: Suprapubic Catheter Drainage

Upper Urinary Tract: Ureteral Stents and Catheters

Upper Urinary Tract: Nephrostomy Tube

Understanding the fundamentals of urinary tract drainage is essential to every practicing urologist and urology trainee. This chapter covers basic aspects of the indications, devices, and descriptions of the various techniques of urinary tract drainage.

LOWER URINARY TRACT: HISTORIC NOTE

Descriptions of draining bladder urinary retention predate the ancient Egyptian civilization and have surfaced from Asian, Chinese, Egyptian, Roman, Byzantine, and Greek civilizations, emphasizing the long-standing importance of this clinical problem. Reports from ancient times describe catheterization with straws, reeds, polished or waxed rolled-up leaves, and hollow twigs (Mattelaer and Billiet, 1995).

In the Hippocratic writings *On Diseases* (around 400 BCE), the use of a bladder catheter for urinary drainage was considered a basic skill of any physician (Moog et al, 2005a). In the 7th century AD, Paulus Aegineta described bladder drainage with use of a slender silver catheter, a technique that became very popular in medieval times. Remarkably, even in that scientifically naive era, the concept of silver having an antiseptic function was postulated (Mattelaer and Billiet, 1995). The use of silver catheters remained popular until the introduction of natural rubber for the manufacture of urinary catheters. Galen (2nd century AD), Paulus Aegineta (7th century AD), and Avicenna (11th century AD) also describe the use of a catheter to deliver a substance into the bladder to treat several ailments including pyocystis, hematuria, and inflammation (Moog et al, 2005a, 2005b; Madineh, 2009).

The 19th century was pivotal in the evolution of the catheter to the devices we use to this day. Joseph F. B. Charrière introduced the Charrière unit to measure the size of a catheter, a scale which has been adopted worldwide. One French unit equals 0.33 mm in the external diameter (Mattelaer and Billiet, 1995). Mercier invented the coudé-tipped catheter in 1836 (*coudé* means “elbow” in French) (Mattelaer and Billiet, 1995). In 1860 Auguste Nelaton created the Nelaton catheter, a soft tubular rubber bladder catheter with a solid straight tip and one side hole, made of vulcanized rubber (Mattelaer and Billiet, 1995). In the 1930s, Frederick E. B. Foley invented a catheter with an inflatable balloon attached to the catheter tip as a retainment mechanism (Tatem et al, 2013). This represented a foundational development that forms the basis for most lower urinary tract catheters used today.

ANATOMIC CONSIDERATIONS

Thorough knowledge of the relevant anatomy is a prerequisite to performing urinary tract drainage.

Male Urethra

The average length of the male urethra is 17.5 to 20 cm from bladder neck to external urethral meatus from postmortem studies as reported in *Gray's Anatomy* (Standring, 2008). More recent literature, measuring the urethra in vivo with a bladder catheter, confirms these lengths to be quite accurate (Kohler et al, 2008; Krishnamoorthy and Joshi, 2012).

In general, the male urethra is divided into segments: bladder neck or preprostatic urethra, prostatic urethra, membranous urethra, and penile or spongy urethra, which in turn can be subdivided into the bulbous urethra, pendulous urethra, and fossa navicularis. An alternative classification for urethral segments is anterior and posterior urethra; the posterior segment consists of the prostatic and membranous urethra, and the anterior segment equates to the penile urethra.

The caliber of the urethra varies throughout its course. The normal healthy external meatus should allow a 24-F catheter to pass. More proximal portions of the adult urethra have a larger caliber, the largest being the prostatic urethra with a caliber of approximately 32 F. The normal bladder neck is usually of a caliber to allow passage of a 28-F instrument (Davis, 1913).

Female Urethra

In nulliparous, continent women, the urethra and bladder neck reside in the connective tissue of the anterior vaginal wall. The urethra measures approximately 4 cm and can be divided into three segments: the distal segment, mid-urethra, and proximal segment (Wieczorek et al, 2012). In a supine position, the urethra has a downward inclination with a slight angle more horizontally approximately midway, and the mean caliber is approximately 22 F (Uehling, 1978).

INDICATIONS FOR LOWER URINARY TRACT DRAINAGE

The indications for inserting a bladder catheter can conveniently be divided into two categories: therapeutic or diagnostic catheterization.

Figure 6-1. A, Urethral dilators with tapered tip (12 and 18 Fr). B, Close-up. C, Filiform and followers.

The most common indication for transurethral bladder catheterization is for drainage of an acute or chronic urinary retention or postvoid residual volume. Drainage can be accomplished by an indwelling catheter or by intermittent catheterization, depending on the pathology, the recurring need for drainage, and the dexterity of the patient or caregivers. Although ultrasound-based bladder scanners are widely used to estimate postvoid residual urine volume, the most accurate method of measurement is by emptying the bladder with transurethral catheterization. The second most common indication for bladder catheterization is to monitor urinary output. Patients with gross hematuria, regardless of its cause, will often require a catheter for bladder irrigation and drainage of bloody urine and blood clots.

Dilation with urethral catheters is the most commonly used primary treatment in the management of urethral strictures (Bullock and Brandes, 2007). Simple urethral dilation can be performed by blind insertion of a filiform leader followed by coaxial followers of increasing diameter or by passing Council catheters of increasing diameter over a cystoscopically placed guidewire (Fig. 6-1). A recent Cochrane meta-analysis comparing simple dilation with endoscopic urethrotomy and open urethroplasty for urethral stricture was not definitive in providing recommendations surrounding preferred treatment of urethral stricture (Wong et al, 2012). The only randomized trial comparing dilation with urethrotomy reported no significant difference in efficacy and stricture-free rates (Steenkamp et al, 1997; Heyns et al, 1998).

In patients unable to provide a clean urine sample with repeated contamination of a midstream urine sample, single catheterization may be used to obtain an uncontaminated urine sample.

Manometer-tipped catheters are used in urodynamic studies to measure the intravesical and urethral pressure. Thermometer-tipped catheters are occasionally used during prolonged surgeries providing both continuous thermometry and adequate drainage for urinary output measurement.

Intravesical therapy with, for instance, dimethyl sulfoxide for interstitial cystitis (Colaco and Evans, 2013), alum for intractable hematuria (Abt et al, 2013), or Mitomycin C or bacille

TABLE 6-1 Catheter Size Based on Age

AGE IN YEARS	CATHETER SIZE (Fr)
<5	5-8

10-14	10
>14	10-14

Calmette-Guérin (BCG) solution for nonmuscle invasive bladder cancer (van Lingen and Witjes, 2013) is also administered through a transurethral catheter.

In performing retrograde cystography, radiographic contrast material is administered by bladder catheterization to opacify the urinary tract for diagnostic purposes.

In urogenital trauma, which is covered elsewhere in this text, insertion of a bladder catheter is, depending on the extent of the trauma, often the first choice of treatment. This should be considered only after diagnostic workup of the possible urethral trauma has been completed so that the feasibility and appropriateness of transurethral catheter placement can be defined.

CATHETER SELECTION

A wide variety of catheters are available for transurethral catheterization. Differences in materials used in manufacture; variations in length, circumference, shape of the catheter tip, and number of channels; and varieties of coatings contribute to this vast array of such devices.

The choice of catheter design and size depends on the indication for use, expected fluid requiring drainage, anticipated indwelling time, age, gender, previous history, and patient anatomy. One should choose the smallest size available based on these variables (Table 6-1). The use of feeding tubes as urethral catheters should

be discouraged because their stiffness and length can be a source of complications (ischemic ulcers, urethral strictures, and knotting in the bladder) (Smith, 2003; Sarin, 2011).

The optimal catheter for an initial attempt at transurethral bladder catheterization in adult patients with no past urologic history, no risk of urinary tract abnormality, and no known allergies, is a 16-Fr latex straight-tipped catheter.

CATHETER DESIGN

The most basic catheter design is constructed with a single lumen to allow for drainage or instillation. The most frequently used retention mechanism is the retention balloon, which is inflated through a dedicated channel. The three-way catheter allows for simultaneous instillation and drainage of fluids and is especially useful in patients with hematuria, clot retention, and pyuria. Continuous bladder irrigation is most commonly used postoperatively after urologic surgery, when hematuria and possible clot formation are to be expected. The three-way catheter is designed with a larger-than-average balloon to allow for instillation of 30 mL or more, which can be helpful in achieving hemostasis after transurethral resection of the prostate by applying traction on the catheter, thus compressing vessels at the bladder neck (Fig. 6-2).

The addition of channels to the initial single catheter design comes with potentially negative design requirements. The extra lumens occupy space in the internal lumen of the catheter, reducing the internal diameter. The inner diameter of a 24-Fr single-lumen catheter is larger than the inner lumen of a 24-Fr two-way catheter, which in its turn is larger than the inner lumen of a 24-Fr three-way catheter.

There are basically two available tip shapes, the Nelaton blind-ending straight tip and the coude tip, or elbowed or Tiemann tip. Both versions exist in a Councill catheter version, which can be passed into the bladder over a guidewire if necessary. Multiple variations such as tapered tips or multiple side holes exist throughout the wide array of available catheters.

Materials and Coatings

Most catheters for everyday use are composed of latex, rubber, silicone, or polyvinylchloride (PVC). For short-term catheterization, latex or rubber catheters are preferred because of their availability and low cost. Silicone is relatively inert, and randomized controlled trials (RCTs) have demonstrated silicone to induce significantly less tissue inflammation than latex catheters (Nacey et al, 1985; Talja et al, 1990; Schumm and Lam, 2008). Silicone is preferred over latex catheters for long-term catheterization. Silicone catheters are

stiffer and less prone to buckling when encountering resistance (Villanueva et al, 2011).

Several coatings have been studied in an attempt to reduce trauma, urethritis, and catheter-associated urinary tract infection (CAUTI). The use of hydrophilic-coated catheters is of interest for intermittent catheterization. Such catheters have been associated with less discomfort, fewer traumatic catheterizations, and decreased incidence of symptomatic urinary tract infections (UTIs) and urethral strictures (Wyndaele, 2002; De Ridder et al, 2005; Cardenas et al, 2011). A recent meta-analysis by Bermingham was unable to identify a significant difference in the incidence of symptomatic UTIs when comparing different catheter types used for clean intermittent catheterization (CIC). Li and colleagues, on the other hand, in a meta-analysis focusing on the spinal cord injury population, demonstrated that the use of hydrophilic-coated catheters in CIC significantly reduced the UTI and hematuria rates (Bermingham et al, 2013; Li et al, 2013). Because the use of clean uncoated catheters for CIC was most cost-effective and the use of gel-reservoir was second most cost-effective in the Bermingham analysis (Bermingham et al, 2013), **the routine use of hydrophilic catheters for CIC in non-spinal cord injury patients is not recommended.**

Antibiotic-impregnated catheters may delay bacteriuria in short-term catheterization (<1 week). Such benefit has not been substantiated in patients requiring longer-term catheterization (Schumm and Lam, 2008; Hooton et al, 2010).

Bacterial-coated catheters have the theoretic benefit of colonizing the urine with a nonvirulent strain of *Escherichia coli* and have shown promising results in small pilot trials. Studies on the feasibility and efficacy of clinical use of such catheters are ongoing (Trautner et al, 2007; Prasad et al, 2009; Darouiche and Hull, 2012).

A 2008 Cochrane meta-analysis demonstrated that the use of silver-alloy-coated catheters significantly reduced the incidence of asymptomatic bacteriuria in short- and long-term (>1 week) use of such catheters (Schumm and Lam, 2008). In a more recent multicenter RCT including more than 6000 patients, antimicrobial-coated catheters demonstrated a statistically significant benefit in reducing CAUTI compared with polytetrafluoroethylene (PTFE)-coated catheters, whereas silver-alloy catheters demonstrated no beneficial effect. **Because no clinically significant benefit was noted for short-term catheterization with either catheter, the routine use of these catheters cannot be recommended (Pickard et al, 2012).**

New coatings to enhance biocompatibility are still being developed and investigated, with the desired outcome being coatings that prevent encrustation and UTIs (Siddiq and Darouiche, 2012).

TECHNIQUE OF URETHRAL CATHETERIZATION

After establishing the indication for catheterization, a medical and surgical history, including allergies, focusing on previous urologic history, surgeries, and catheterization attempts should be obtained. This information is necessary for optimal catheter choice and complication risk assessment.

When performing urethral catheterization, the physician assumes a position at the side of the patient corresponding to the physician's dominant hand (if the physician is right handed, the position is on the right-hand side of the patient). All materials expected to be required should be readily available on the sterile drape. The patient should be in supine position at a comfortable height for the individual performing the catheterization. A frog-leg position is preferred for female patients. Catheterization should be carried out in a sterile fashion and should start with sterile draping of the patient. When an indwelling catheter is being placed, the balloon should be checked for integrity before catheterization.

The most recent American Heart Association guidelines no longer recommend routine use of infective endocarditis prophylaxis for any genitourinary procedure, even in patients with the highest-risk cardiac conditions (Wilson et al, 2007).

Figure 6-2. Three-way, two-way, and single-lumen catheters.

Lubrication of the catheter is advised for smooth catheterization and minimization of risk of urethral trauma. Four categories of lubricants exist: plain lubricant, lubricant-anesthetic, lubricant-disinfectant, and lubricant-anesthetic-disinfectant.

The use of 2% lidocaine urethral instillation before instrumentation was first reported safe and efficacious in the mid-20th century (Haines and Grabstald, 1949; Persky and Davis, 1953) and is still widely practiced; however, evidence of benefit has been a topic of conflicting literature.

The safety of urethral lidocaine use has been well established in situations in which the urethra is intact. The systemic uptake of lidocaine through intact mucosa after instillation of doses of up to 550 mg (approximately 27 mL of 2% lidocaine lubricant) reaches a very low peak concentration that never reaches a toxic level (Ouellette et al, 1985; Eardley et al, 1989; Birch and Miller, 1994). However, toxicity has been reported in patients in whom lidocaine gel was used in the presence of a disrupted mucosal barrier, leading to a high peak serum concentration within minutes. Reported symptoms are confusion, lethargy, seizures, disorientation, and anaphylactic shock (Sundaram, 1987; Clapp et al, 1999; Priya et al, 2005; Sinha and Sinha, 2008).

Chitale and McFarlane showed no difference in pain experience during flexible cystoscopy after plain or anesthetic lubricant (McFarlane et al, 2001; Chitale et al, 2008). Ho and coworkers concluded that insertion of an anesthetic lubricant is paradoxically more painful than plain lubricant (Ho et al, 2003). Cooling the lubricant to 4° C has been shown to significantly decrease pain perception compared with lubricant at room or body temperature, possibly because of a cryoanalgesic effect (Thompson et al, 1999; Goel and Aron, 2003).

The anesthetic lubricant should be indwelling in the urethra longer than 15 minutes to provide a beneficial effect (Choong et al, 1997; Siderias, 2004). A short delay (<15 minutes) does not seem to have any benefit compared with no delay (Birch et al, 1994; Garbutt et al, 2008; Losco et al, 2011). In female catheterization, the use of an anesthetic lubricant has been shown to be effective even after only several minutes of indwelling time (Chan et al, 2013; Chung et al, 2007).

Two available meta-analyses on the use of anesthetic versus non-anesthetic lubricant report conflicting results and recommendations, possibly because of different inclusion criteria and a high grade of heterogeneity in included studies. Patel and colleagues demonstrated no difference in use of anesthetic versus plain lubricant; in contradistinction, Aaronson and colleagues reported a statistical beneficial effect (Patel et al, 2008; Aaronson et al, 2009).

Considering the conflicting data available, the routine use of anesthetic lubricant cannot be recommended. If anesthetic lubricant is to be used, the limited evidence available suggests slowly instilling (3 to 10 seconds) a minimum amount of 20 mL of cooled lubricant and allowing a minimum of 15 minutes of exposure to maximize benefit to the patient (Schede and Thüroff, 2006; Tzortzis et al, 2009).

Catheterization in Male Patients

The true external urethral meatus is exposed by retracting the foreskin if present. In the presence of phimosis, catheterization can be attempted blindly with a smaller-gauge flexible catheter. Hypospadias is not uncommon, and some hypospadiac patients have a blind-ending navicular fossa, which should not be catheterized.

If a meatal stricture or stenosis is apparent, passing a catheter of a smaller size should be attempted first. Gentle dilation of the stenosis with sounds can be attempted if catheterization is unsuccessful.

After skin and meatus preparation and sterile draping, the initial maneuver is to grasp the penis with the nondominant hand, which is from then on regarded as no longer sterile. The pendulous curvature of the penis is eliminated by pulling the shaft upward. The catheter is inserted into the meatus after lubrication and advanced approximately 7 to 12 cm. The penis should be brought into a horizontal position, parallel to the patient. Some slight resistance can be appreciated at the membranous urethra, the most fragile

segment. The entire catheter is introduced into the penis, up to the bifurcation of the catheter and balloon valve. Spontaneous drainage of urine should occur if the bladder is not empty. If no spontaneous urine drainage appears, gently pushing down on the suprapubic region or instilling a small amount of clear sterile fluid and aspirating the catheter with a syringe should result in drainage. The lumen of the catheter can be obstructed with lubricant jelly, pus, or blood. If after such maneuvers no drainage occurs, the bladder is empty or the catheter is malpositioned.

After verifying the correct position of the catheter in the bladder, inflate the balloon with sterile water, which has been demonstrated to be the optimal filling solution, especially if the catheter is to be in place for several days or longer (Sharpe et al, 2011). Although not conclusively proven, saline or glucose-based solutions can theoretically occlude the tubing by precipitation (Hui et al, 2004; Huang et al, 2009). In uncircumcised patients, the foreskin is reduced to its normal position to avoid paraphimosis.

The penis and catheter should be taped in an upright position to prevent pressure ulceration from occurring at the curve in the pendulous urethra and iatrogenic hypospadias at the urethral meatus. Iatrogenic hypospadias, when missed or untreated, can evolve into severe deformations (Andrews et al, 1998; Gokhan et al, 2006; Cipa-Tatum et al, 2011).

Ideally, a closed circuit should be maintained with the catheter connected to a sterile closed bag system, positioned lower than the bladder to allow gravity to assist in bladder emptying.

Although it is believed that rapid complete emptying of a urinary retention results more frequently in possible complications such as hematuria, hypotension, or pain, **efficient complete emptying has been demonstrated to be safe and is recommended** (Nyman et al, 1997; Muhammed and Abubakar, 2012).

Catheterization in Female Patients

With the patient in a frog-leg position and adequately draped, the nondominant hand is used to spread the inner labia to reveal the external urethral meatus. This hand is now considered contaminated. The urethral meatus should be found 1 to 2.5 cm inferior to the clitoris. After the meatus has been cleaned and lubricated, the catheter is inserted into the meatus and gently advanced until approximately half the catheter has been inserted. It is not necessary to advance the catheter up to the valve bifurcation. The balloon is inflated after confirming the correct position of the catheter in the bladder.

Catheterization in Children

Catheter use in children is predominantly for diagnostic purposes or postoperative drainage. In infants, suprapubic puncture for obtaining a urine sample is often preferred over a bag sample because it is more likely to be sterile. Bladder catheterization, however, is preferred over suprapubic aspiration because it is less painful and has a higher success rate in obtaining a satisfactory urine sample (Pollack et al, 1994; Kozar et al, 2006; El-Naggar et al, 2010). Portable bedside bladder ultrasound is useful to identify a sufficient amount of urine in the bladder before attempted catheterization (Chen et al, 2005; Robson et al, 2006; Baumann et al, 2008).

Children are presented with a phimosis more frequently than men. As in adults, it is useful to align the preputial opening with the meatus to facilitate catheterization. Compared with women, the urethral orifice in young girls may be partly obscured behind the hymen. To reveal the meatus, it is useful to apply some downward pressure on the hymen. If the meatus cannot be visualized, the same maneuver as in women should be applied: the tip of the catheter is slid down from the clitoris toward the introitus, above the hymen.

Difficult Catheterization

The most commonly encountered cause of difficult catheterization in men without previous relevant history is inability to pass the

catheter beyond the prostate. This is commonly the result of an enlarged prostate or a closed striated sphincter. The attempted catheter is retracted, and the catheter tip evaluated for the presence of blood. If the catheter tip is clean, the next option is a 14-Fr or 16-Fr silicone catheter because it is somewhat stiffer and may pass the slight resistance more effectively. If blood is present at the catheter tip, there is a possibility of a false passage and a coudé-tipped catheter should be used for the next attempt. A false passage is most commonly created in the membranous urethra, the most fragile segment of the urethra, which can be palpated transrectally at the apex of the prostate. One can try guiding the catheter past the false passage transrectally with the index finger. If transrectal guidance does not facilitate passage and if the caliber of the urethra allows, placement of a small-caliber catheter (10 or 12 Fr) in the false passage may be attempted. This may close off the false passage and allow for passage of a second transurethral catheter into the bladder. If passage of a catheter is still not possible, a flexible cystoscope is used to assess the urethra for size, strictures, false passage, or bladder neck stenosis. If the bladder is successfully accessed, a guidewire can be passed and used to pass a Councill catheter. If a stricture is apparent and cannot be catheterized with a smaller catheter, a guidewire is cystoscopically passed through the stricture into the bladder, and the urethra dilated to allow for a catheter of adequate size to be placed. If the urethral stricture is a new diagnosis, this should be documented with a view toward follow-up and treatment if necessary. The use of stylets is recommended only in experienced hands and only if cystoscopic guidance is unavailable. If all attempts at urethral catheterization including with flexible cystoscopy guidance are unsuccessful and there are no absolute contraindications, one should consider placing a suprapubic catheter (Fig. 6-3).

Although the female urethra is short, catheterization can be challenging because of inability to find the urethral meatus. In obese patients or in patients unable to assume the frog-leg position, the use of stirrups and assistance for retraction to optimize visualization is advised and may be useful.

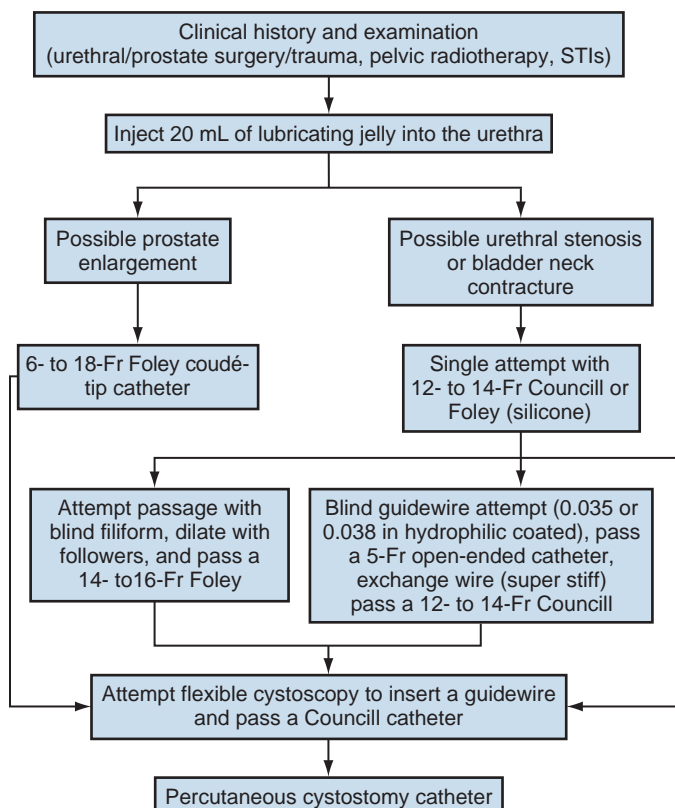

Figure 6-3. Flowchart for managing difficult catheterization. STIs, sexually transmitted infections.

In rare instances such as extreme labial adhesions, introital stenosis, or stricture or stenosis of the female urethra, urethral catheter placement is sometimes not feasible. The same approach as described for male urethral stricture should be applied.

COMPLICATIONS

Catheterization of the urethra is an everyday practice on almost every hospital ward. It is an intervention of significance, however, that may be associated with short- and long-term complications.

From 15% to 25% of hospitalized patients undergo a urethral catheter placement at some point during their stay (Glynn et al, 1997). UTIs account for approximately 35% of hospital-acquired infections, with almost 95% of UTIs in the intensive care unit setting resulting from bladder catheters (Richards et al, 2000; Klevens et al, 2007). Overuse of bladder catheterization has been reported to range from 15% to 40% of cases and is correlated with prolonged hospital stay (Apisarnthanarak et al, 2007; Tiwari et al, 2012). In the United States, the economic impact associated with CAUTI accumulates to an annual cost of about \$300 million (Zimlichman et al, 2013). Implementation of quality improvement and awareness projects has contributed to significantly reducing the incidence and duration of catheterization, and ultimately CAUTI rates (Janzen et al, 2013; Parry et al, 2013; Saint et al, 2013).

As of 2009, the definition for CAUTI was modified to exclude asymptomatic bacteriuria (Dudeck et al, 2011). In current guidelines, a CAUTI is defined as significant bacteriuria in a patient with symptoms or signs indicating a UTI, whereas asymptomatic bacteriuria refers to significant bacteriuria in asymptomatic patients. Asymptomatic bacteriuria does not require antibiotic treatment. Because there is no evidence supporting that treatment of asymptomatic bacteriuria provides any benefit in reducing morbidity or mortality, the European Association of Urology (EAU) and Infectious Diseases Society of America (IDSA) guidelines specifically recommend against screening and treatment of asymptomatic bacteriuria (Tenke et al, 2008; Hooton et al, 2010). The most important risk factor for developing CAUTI is prolonged catheterization (longer than 6 days). Other risk factors include catheterization outside of the operating room, female sex, body mass index (BMI) greater than 30, diabetes, and other active site of infection (Maki and Tambyah, 2001; Stenzelius et al, 2011).

Universal recommendations in guidelines for preventing CAUTI are avoidance of catheter use, maintenance of a closed drainage system, and removal of a catheter as soon as deemed possible. Catheters should be placed under antiseptic conditions, placing the smallest possible catheter with adequate lubrication. Routine irrigation should be avoided (Gould et al, 2010; Hooton et al, 2010; Tambyah and Oon, 2012).

A recent Cochrane meta-analysis showed no difference in urinary infection rates in long-term catheterized patients when different catheter types were compared (Jahn et al, 2012). There is insufficient evidence to reliably recommend the use of one catheter type over another.

Short-term antibiotic treatment (5 days) with catheter exchange has been proven to be equally as effective as long-term treatment (10 days) without catheter exchange in treating CAUTI (Darouiche et al, 2014).

Long-term antibiotic prophylaxis has not been demonstrated to significantly reduce symptomatic CAUTI in patients performing CIC. Interrupting long-term prophylaxis in spina bifida patients results in a nonsignificant increase in UTIs, without clinical significance (Wolf et al, 2008; Hooton et al, 2010; Zegers et al, 2011). Use of prophylactic antibiotics on removal of a bladder catheter, even after short-term catheterization, has been both recommended and discouraged (Wolf et al, 2008; Hooton et al, 2010). American Urological Association (AUA) guidelines published in 2008 recommended the use of antibiotic prophylaxis after catheter removal if bacteriuria is present, particularly in patients with risk factors such as advanced age, immunodeficiency, or corticosteroid use (Wolf et al, 2008). In 2010 the IDSA discouraged the use of prophylactic

antibiotics before catheter removal or catheter change (Hooton et al, 2010). The most recent meta-analysis attempting to answer this question reports a reduction in UTI incidence when antibiotic prophylaxis is administered on removal of a bladder catheter in surgical patients (Marshall et al, 2013). Taking into consideration that up to 25% of hospitalized patients are catheterized at some point during their stay, recommending the **routine use of antibiotics after catheter removal** would entail an enormous usage of antibiotics with the associated risks of bacterial resistance and other drug-related side effects. Therefore, prophylaxis **should be considered a recommendation only in patients with risk factors**, as previously stated by the AUA guidelines panel.

A comprehensive overview and meta-analysis of all possible complications of urethral catheterization reports that noninfectious complications are at least as frequent as CAUTI in short-term catheterizations and up to four times more prevalent in long-term catheterizations. Complications include pericatheter urine leakage, accidental removal, catheter blockage, hematuria, bladder stones, and bladder cancer. The subgroup of patients with spinal cord injuries is at greater risk of complications (Hollingsworth et al, 2013).

Inability to remove a transurethral bladder catheter can be a challenging complication. Entrapment of the catheter by anastomotic sutures after urethroplasty or radical prostatectomy poses a unique postoperative complication. When sutures are known to be degradable, one can retry catheter removal 1 or 2 weeks after the initial attempt. If the sutures are nondegradable, the urethra can be accessed with a semirigid ureteroscope to visualize and divide the suture with laser energy (Nagarajan et al, 2005; Nagele et al, 2006). Cuffing of the balloon after deflation can cause the catheter to bind at the bladder neck. This phenomenon is dependent on the catheter used (material and manufacturer), indwelling time, urinary infection, and deflation method, with indwelling time being the most significant predictor. Slow deflation of the balloon and the use of hydrogel-coated or PTFE catheters reduce the chance of balloon cuffing (Chung and So, 2012). Gonzalgo proposed a technique of instillation of 0.5 to 1 mL of fluid in the balloon to smooth out the cuff for easier catheter removal (Gonzalgo and Walsh, 2003).

Inability to deflate the Foley balloon is not uncommon. Resolution of this problem may be achieved by instilling an extra 1 or 2 mL of fluid in the balloon and trying to repeat aspiration. Overinflation of the balloon with the intention of having it burst should be avoided because this may be painful and possibly result in retained fragments of the catheter balloon in the bladder. Cutting off the inflation valve may assist if the valve is not functioning correctly. If the balloon still does not deflate, one can pass a guidewire through the inflation channel to try and perforate the balloon. If all else fails, ultrasound-guided needle puncture of the balloon is typically the final approach. Inability to remove a catheter with a fully deflated balloon can also be caused by catheter encrustation, especially if the catheter has been indwelling for an extended time. There is strong evidence that the main causal factor of catheter encrustation is infection with *Proteus mirabilis*. Especially in patients with long-term bladder catheterization, this circumstance can cause recurrent blockage of the catheter (Stickler and Feneley, 2010). Applying gentle traction to the catheter can cause the encrustation to dislodge, facilitating catheter removal. If this does not solve the problem and encrustation is suspected, ultrasound or x-ray imaging can be used for confirmation. For more significant encrustations, one can consider using a semirigid ureteroscope and the holmium:YAG laser to remove the encrustation material. Increasing patient fluid intake and ingestion of citrate could delay or control this problem in known stone formers and chronic catheter blockers (Stickler and Feneley, 2010).

Urethral stricture is not an uncommon complication after catheterization. Lumen and colleagues reported that 11.2% of urethral stricture disease requiring urethroplasty is causally related to urethral catheterization. When site of stricture was taken into account, history of urethral catheterization was the most important causal factor of multifocal or panurethral strictures (Lumen et al, 2009).

Fenton and associates reported 32% of urethral strictures as being caused by iatrogenic trauma; 36.5% of these were the result of prolonged catheterization. The authors proposed that prolonged catheterization leads to urethral inflammation and ischemia, and ultimately to urethral stricture (Fenton et al, 2005).

Inflation of the balloon in the prostatic urethra or in a false passage can cause severe hematuria, urethral rupture, and subsequent stricture (Lang et al, 2012).

Prevention of Iatrogenic Trauma

The pressure in the catheter balloon when an incorrectly placed catheter is being inflated is much higher than when the catheter is in a correct position. Forces of extraction of a catheter are much lower with 5 mL in the balloon than with 10 mL in the balloon (Wu et al, 2012). When high pressure is perceived when inflating the balloon, one should reassess and ensure that the catheter is in the bladder. In patients at risk of inadvertent traumatic catheter extraction, the balloon is filled with 5 mL instead of 10 mL to decrease the chance of significant urethral trauma.

When prolonged catheterization is required, a smaller catheter, such as 16 Fr, should be used. There should be a lower threshold for placing a suprapubic catheter when prolonged catheterization is anticipated (Fenton et al, 2005). With training and education, trauma from urethral catheterization can be reduced fivefold (Kashefi et al, 2008; Thomas et al, 2009).

LOWER URINARY TRACT: SUPRAPUBIC CATHETER DRAINAGE

Indications

If bladder drainage is necessary but access to the bladder cannot or should not be obtained transurethrally, the placement of a suprapubic catheter should be considered.

During transurethral resection of the prostate, suprapubic catheter placement is preferred by some urologists because a continuous flow can be maintained at all times without influencing bladder pressure (Sánchez Zalabardo et al, 2003).

Short-term suprapubic catheter placement is often useful in postoperative situations after urogenital surgery to allow for bladder or urethral tissue healing. Although a suprapubic catheter is more invasive than a transurethral catheter, evidence suggests that the former is more acceptable than a transurethral catheter to surgical patients (McPhail et al, 2006). There is **insufficient evidence supporting superiority of a suprapubic catheter over a transurethral catheter in short-term postoperative catheterization** (Phipps et al, 2006). However, when considering the population of hospitalized patients in need of short-term catheterization (up to 14 days), a significant benefit has been found in favor of the suprapubic catheter in terms of bacteriuria incidence and patient comfort (Niël-Weise and van den Broek, 2005).

In patients requiring a long-term indwelling catheter in whom CIC is not feasible, a suprapubic catheter is often a better option than a transurethral catheter. A recent Cochrane meta-analysis did not identify any eligible trials for analysis to determine whether a transurethral or suprapubic catheter is better in terms of effectiveness, complications, cost-effectiveness, and quality of life in long-term catheterized patients (Jamison et al, 2011; Niël-Weise et al, 2012). This reflects the lack of evidence-based data and limits the recommendation of a suprapubic catheter over a transurethral catheter for long-term catheterization.

Long-term suprapubic catheter placement in infants or children is rarely necessary. Whenever suprapubic catheter placement in children is required, the use of ultrasound guidance during the catheter placement is advised.

Contraindications to suprapubic catheter placement include previous lower abdominal surgery resulting in unsafe percutaneous passage to the bladder, bladder cancer, uncorrected coagulopathies or anticoagulation, abdominal wall infection at the desired

puncture site, and the presence of vascular grafts near the preferred tract (Harrison et al, 2011).

In patients in whom one may suspect the presence of ascites, ultrasound is always used to confirm a large postvoid residual urine volume because ascites can sometimes be mistaken for a large post-micturitional volume on ultrasound bladder scan.

Advantages of a suprapubic catheter include elimination of risk of urethral stricture and penile erosion. A trial to void can be attempted without the need for recatheterization if unsuccessful. Wound care for a suprapubic catheter is often easier, especially in chair-bound patients.

In patients requiring long-term catheter drainage, the placement of a suprapubic catheter as an alternative to a transurethral catheter can be considered, and advantages and disadvantages should be discussed with the patient.

Technique of Suprapubic Catheter

Placement: Percutaneous

For suprapubic catheter placement, the patient should be placed in supine position at a comfortable height for the physician.

In most patients the distended bladder displaces the intraperitoneal bowel loops out of the pelvis and away from the pubic symphysis. A minimum bladder volume of 300 mL on bladder scan is advised before suprapubic catheter placement is attempted (Albrecht et al, 2004).

The patient's infraumbilical abdomen should be prepared and draped in a sterile fashion. In performing blind puncture, the symphysis should be palpated and the access site should be chosen approximately one to two fingerbreadths above the symphysis. In obese patients with an abdominal pannus, placement of the tract in a skin fold is avoided to prevent dermatitis (Harrison et al, 2011). Local anesthetic is injected into the skin and along the preferred trajectory using a 10- to 20-mL syringe and an 18-gauge needle. The tract should be almost perpendicular to the skin. Aspirating urine will confirm access to the bladder. A midline 5- to 10-mm transverse incision is made at the injection site.

The safest technique for catheterization is the **Seldinger technique**. A floppy-tip guidewire is advanced into the bladder through an 18-Fr access needle. The percutaneous tract is dilated with coaxial dilators. A Cope loop or Councill catheter can be placed over the guidewire into the bladder after the tract is dilated (Fig. 6-4).

The **trocár technique** employs a peel-away trocar that envelops the catheter. The trocar should be advanced firmly but under steady control of the trocar. Once entry into the bladder has been confirmed by urine flashback or aspiration, the catheter is advanced completely into the bladder, and the trocar is retracted and peeled away. If the suprapubic catheter does not have a retention mechanism, the catheter is sutured to the skin.

Obesity, previous lower abdominal or pelvic surgery or radiation therapy, and a nondistended bladder that cannot be palpated should prompt the physician to use ultrasound guidance. It is preferable to have an assistant operate the ultrasound probe, thus allowing both hands to be available for catheter placement. When the bladder is being punctured, the needle tip will appear as a hyperechoic structure on the ultrasound image (Jacob et al, 2012). The use of ultrasound-guided suprapubic catheter placement has a high success ratio, and the procedure is safe and has a low complication rate (Cronin et al, 2011). Cystoscopic visual guidance can be of additional help in performing percutaneous suprapubic catheter placement.

Technique of Suprapubic Catheter Placement: Open

Open suprapubic catheter placement should be undertaken when a percutaneous technique cannot be performed safely. After the infraumbilical abdomen is prepared and draped, a small incision is made about one to two fingerbreadths above the pubic symphysis, providing access to the retroperitoneal space of Retzius. Two stay sutures are placed to stabilize the bladder, and a small incision is

Figure 6-4. Percutaneous suprapubic catheter kit. *Left to right, Guidewire, drainage bag connection tubing, Cope loop catheter, Amplatz dilators, and cystostomy needle.* (Courtesy Cook Medical, Bloomington, IN.)

made through the bladder wall between the sutures, allowing for easy passage of a 16- to 18-Fr catheter. The catheter should be introduced through the skin in line with the bladder incision to prevent kinking and should be secured in the bladder with a purse suture to prevent urine extravasation.

Because of the invasiveness of suprapubic catheter placement and its transcutaneous character, it is subject to complications such as wound infection, hematoma, and perivesical fluid collection. **Surrounding organ injury is the most severe complication and has been reported to occur in less than 1% to 2.7% of procedures** (Sheriff et al, 1998; Ahluwalia et al, 2006; Cronin et al, 2011).

Catheter Exchange

Before exchanging a suprapubic catheter, it should be left in place for at least 2 to 4 weeks to allow for tract maturation. After the patient has been prepared and all required materials are readily available, the physician deflates the balloon and extracts the catheter. Some lubricant gel is instilled in the tract, and the new catheter is placed into the bladder. A small amount of fluid in the bladder adds safety by providing the possibility of aspirating the catheter to ensure correct placement. Catheter exchange over a guidewire can be performed in patients with difficult tracts.

Complications

Complications from the presence of the suprapubic catheter are similar to those of a transurethral catheter. A meta-analysis comparing suprapubic to transurethral drainage after gynecologic surgery concluded that suprapubic catheterization significantly reduces the rate of UTI but, on the other hand, was significantly correlated with a higher rate of minor complications such as hematuria, leakage, blockage, or accidental catheter loss. Superiority of one over the other could not be determined (Healy et al, 2012, 2013).

Frequent blockage of a suprapubic catheter can be caused by encrustation or bladder stones. Frequent catheter blockage should prompt consideration of cystoscopy to evaluate for the presence of bladder stones. Excessive granulation tissue at the suprapubic tract can be treated by silver nitrate application.

Catheter placement technique with a trocar or Seldinger technique, catheter type, and catheter size do not seem to influence the complication rate of ultrasound-guided suprapubic catheterization (Cronin et al, 2011).

Bowel perforation during catheter exchange has been reported and has been associated with difficult exchange and use of stiffer catheters (Mongiu et al, 2009; Kass-Iliyya et al, 2012).

An accidentally removed suprapubic catheter is a unique, sometimes challenging complication. Pigtail or Cope loop catheters are more prone to dislodgement than balloon retained catheters (Cronin et al, 2011). The tract of the suprapubic catheter can close in a short period of time, encouraging prompt tube replacement. Smaller catheters, guidewire placement, and dilation of the tract can be of assistance for catheter replacement.

Although there is no available literature on learning curve in suprapubic catheter placement, practice and experience are expected to translate to a lower complication rate. Hossack recently proposed the first design of a simple, useful, and cheap training model for percutaneous suprapubic catheter placement for practitioners to gain experience before placing suprapubic catheters in patients (Hossack et al, 2013).

UPPER URINARY TRACT: URETERAL STENTS AND CATHETERS

Historic Note

The use of ureteral stents in surgery was described as early as the 19th century (Shoemaker, 1895). The first urologist to access the ureter endoscopically was Dr. James Brown at Johns Hopkins Hospital in 1893 (Arcadi, 1999). Zimskind, however, in 1967 was the first to describe the cystoscopic placement of indwelling ureteral stents for obstructed ureters (Zimskind et al, 1967). At that time, stents were very prone to migration and device expulsion, which deterred widespread adoption. Gibbons was the first to patent a barbed stent as a self-retaining mechanism (Gibbons et al, 1976). The first “double-J” (DJ) or double pigtail stent was developed

almost simultaneously by Finney and Hepperlen (Finney, 1978; Hepperlen et al, 1978). After this novel advance, the use of DJ stents increased dramatically in urology departments worldwide, which had a tremendous positive impact on endourologic surgery and patient care. Today, ureteral stents are of fundamental importance to any urologic practice.

Stent Technology

The ideal stent is easy to insert, has the ability to relieve intraluminal and extraluminal obstruction, has excellent flow characteristics, is resistant to encrustation and infection, is chemically stable after implantation in a urinary environment, and does not induce patient symptoms. Stents should therefore have high tensile strength, a low friction coefficient, memory, and a self-retainment mechanism and should be both biocompatible and affordable. The number of new patents filed annually related to ureteral stents is shown in Figure 6-5 and demonstrates that development of new designs, biomaterials, and coatings for ureteral stents has increased dramatically over the past decade. This effort reflects the many initiatives in stent design aligned to achieve the ideal characteristics.

Biomaterials

Early ureteral stents were manufactured from silicone (Zimskind et al, 1967). Although silicone is the most biocompatible material tested to date (Beiko et al, 2003; Watterson et al, 2003b), the high friction coefficient and flexibility that are characteristic of silicone make silicone stents more difficult to navigate through a tortuous or obstructed ureter. Polyethylene was introduced as the first plastic polymer in the commonly used DJ stents (Mardis et al, 1979). Polyethylene stents become brittle after prolonged exposure to the urinary environment and are prone to encrustation, blockage, and fragmentation, leading to the discontinuation of use of this material in stent manufacture and the development of newer polymers. Currently used stents are commonly composed of polyurethane, silicone, or proprietary copolymers such as Silitek (Surgitek, Medical Engineering Company, Racine, WI), C-Flex (Cook Medical,

Figure 6-5. Graph showing annual number of patents filed related to ureteral stents. (Courtesy Dolcera Patent and Market Research Services.)

Bloomington, IN), Percuflex (Boston Scientific, Marlborough, MA), or Tecoflex (PNN Medical, Kvistgaard, Denmark).

Ureteric obstruction caused by extrinsic, usually malignant, compression requires stents that can withstand these radial compressive forces. Mechanical tests on nonmetal stents evaluating resistance to radial compression demonstrated the C-Flex (Cook Medical, Bloomington, IN) stent to resist extrinsic compressive forces best (Hendlin et al, 2006). Although it is common practice to use a larger-lumen stent to achieve adequate drainage, stents with a smaller lumen have been shown to be more resistant to radial compressive forces in experimental studies (Hendlin et al, 2006).

The self-expanding metallic Wallstent has been used to treat ureteric obstruction since 1992 (Pauer and Lugmayr, 1992). Although the stent is reported to be safe and effective, its primary patency rates are low, ranging from 29% to 54% at 3 to 12 months, mainly because of hyperplastic tissue ingrowth. With additional endoscopic interventions, secondary patency can be maintained in up to 100% of stents in short- and long-term follow-up (Flueckiger et al, 1993; Lugmayr and Pauer, 1996; Lang et al, 1998, 2013).

The Resonance metallic ureteral stent (Cook Medical, Bloomington, IN) is constructed from tightly coiled spirals of a corrosion-resistant nickel-cobalt-chromium-molybdenum alloy wire and is designed to resist encrustation and tissue overgrowth. Although the overall flow was inferior compared with conventional stents in an in vivo porcine study, the Resonance stent can easily withstand compression forces that completely obstruct conventional stents (Blaschko et al, 2007; Pedro et al, 2007). Long-term results and follow-up in larger cohorts demonstrate a failure rate of 28% to 35%, which is comparable to conventional stents (Liatsikos et al, 2010; Goldsmith et al, 2012; Kadlec et al, 2013). Because the Resonance stent can be safely retained in the ureter for extended periods, the reduced hospital and procedure costs may mitigate the higher cost of the stent itself (López-Huertas et al, 2010; Polcari et al, 2010; Taylor et al, 2012).

Newer metal stents have been designed and tested in vitro and are awaiting clinical trials. The Silhouette stent (Applied Medical Resources Corporation, Rancho Santa Margarita, CA) is a soft, coil-reinforced stent with a hydrophilic coating. It is less prone to kinking than other stents and can resist higher compressional forces than the Resonance stent, theoretically resulting in a lower chance of stent failure (Pedro et al, 2007; Christman et al, 2010; Miyaoka et al, 2010). The Passage and Snake stents (ProSurg, San Jose, CA) are open-ended and less tightly coiled than the Resonance and Silhouette stents, allowing for more flexibility. Both stents sustain higher extrinsic radial compression forces than the Silhouette stent and have lower tensile strength (Hendlin et al, 2012).

The Memokath 051 ureteral stent (PNN Medical, Kvistgaard, Denmark) is a nickel-titanium alloy (nitinol) stent with a

thermo-expandable anchoring mechanism. The initial report on the use of the Memokath stent in obstructed ureters demonstrated a high patency rate of the lumen after 10.6 months of follow-up (Kulkarni and Bellamy, 1999). In addition to having long-term patency in ureteral obstruction, the Memokath 051 is better tolerated than conventional ureteral stents in terms of urinary symptoms, pain, and general health (Maan et al, 2010). Late complications include stent migration in 15% to 18% and encrustation in 3% to 5%. Stent manipulation or reinsertion has been reported to be necessary in 20% to 25% of patients (Agrawal et al, 2009; Papatsoris and Buchholz, 2010).

The Uventa stent (Taewoong Medical, Gimpo, South Korea) is also a nickel-titanium alloy, segmental, thermally expandable stent. A PTFE coating is positioned between the outer and inner mesh. The outer mesh provides extra friction to prevent stent migration, and the PTFE coating prevents hyperplastic stent ingrowth (Chung et al, 2008). Kim reported a 100% primary patency in 20 stents with an average follow-up of 7.3 months (Kim et al, 2012). After a 10-month follow-up period, primary patency rates decrease to 64.8% and secondary patency rates to 81.7%. Stent failure is predominantly a result of tumor progression at an adjacent ureteral segment. Migration has not been reported (Chung et al, 2013).

The Allium stent (Allium Medical Solutions, Israel) is a large-caliber (24 Fr or 30 Fr) nickel-titanium alloy, expandable mesh stent coated with a biocompatible polymer to prevent stent ingrowth. The Allium stent was specifically developed for use in the distal ureter and has an intravesical anchor to facilitate removal. Limited data are available in the published literature, reporting patency rates of greater than 95% and migration in 14% of stents, necessitating removal. No encrustation was documented at an average of 17-months' follow-up (Moskovitz et al, 2012; Leonardo et al, 2013) (Fig. 6-6).

A common problem among metal mesh stents is reduced patency in long-term follow-up and late complications such as migration, encrustation, and erosion. Coatings to prevent hyperplasia and stent ingrowth in metal mesh stents have been adopted from the endovascular stent realm. In comparison to uncoated metal mesh stents, a paclitaxel drug-eluting metal mesh stent was shown to generate less inflammation and hyperplasia of the surrounding tissue in a porcine model (Liatsikos et al, 2007). The zotarolimus-eluting metal stent induced a significantly lower hyperplastic reaction without influencing inflammation rates in a porcine and rabbit model (Kallidonis et al, 2011). These coatings have the potential to improve patency and reduce complication rates.

The development of a biodegradable stent could theoretically eliminate the need for cystoscopic stent removal and could help prevent the occurrence of forgotten stents. Biodegradable materials are composed of high-molecular-weight polymers such as

Figure 6-6. Different stent designs. A, Polaris Loop stent, Polaris Ultra stent, Percuflex Plus stent, and Contour VL stent. B, Resonance metal stent. (A, Courtesy Boston Scientific, Marlborough, MA; B, courtesy Cook Medical, Bloomington, IN.)

polylactide or polyglycolide. Surface modification of bioresorbable polymers with, for instance, hydroxyethylmethacrylate (HEMA), oligo(ethyleneoxide)-monomethacrylate (OEOMA), or acrylic acid (AAc) results in improved biocompatibility without toxicity of these polymers and thus allows use in a urinary environment (Brauers et al, 1998). The main challenge of biodegradable materials is controlling the rate of degradation. In vivo tests with a poly-L,D-lactide polymer in a canine model demonstrated promising results with complete degradation of all stents within 24 weeks without induction of ureteral histologic changes (Lumiaho et al, 1999, 2000).

In vivo tests in a porcine model with Uripren, a biodegradable copolymer composed of L-glycolic acid, polyethylene glycol, and barium sulfate, show promising preliminary results. With the current chemical formulation, Uripren stents reliably achieve degradation after 4 weeks. The Uripren stents induced a lower degree of ureteral inflammatory change when compared with conventional stents in a porcine model (Hadaschik et al, 2008; Chew et al, 2010, 2013). Olweny and colleagues established that use of a degradable poly-L-lactide-co-glycolide polymer stent in a porcine ureter after endopyelotomy was feasible but induced more tissue inflammation than a conventional stent (Olweny et al, 2002).

Newer polymer components are currently under investigation for future stent development. Magnesium-yttrium alloy potentially offers many benefits over currently existing stents because the alloy is biodegradable and seems to inhibit bacterial viability in vitro. The rate and mode of degradation can be controlled through alloy design and surface modification (Lock et al, 2012, 2014). Degradable polyfilament, fibrous stents composed of polyglycolic acid (PGA) and polylactic acid (PLA) demonstrated complete degradation after 8 weeks. The resistance to compression of the stent was comparable to that of conventional stents during the first 2 weeks after insertion (Shang et al, 2011).

The feasibility of a natural, tissue-engineered ureteral stent has been investigated in vitro with the goal of achieving optimal biocompatibility. Amiel demonstrated that seeding chondrocytes on a polylactic-co-glycolic acid enforced PGA polymer scaffold was feasible in vitro and that the tissue-engineered stents were readily elastic and could withstand compression (Amiel et al, 2001). No in vivo trials have yet been reported.

The first and to date only trial studying the use of biodegradable stents in human subjects demonstrated adequate drainage while maintaining a high patient tolerance. After 90 days, 96.6% of patients were stent free. Three patients, however, required shock-wave lithotripsy (SWL) and one patient subsequently required ureteroscopy (URS) to clear retained stent fragments (Lingeman et al, 2003).

Coatings

Drug-eluting and antiadhesive stent coatings are under investigation with the goal of improving stent handling, reducing biofilm formation, preventing encrustation, and improving patient comfort.

Hydrogel is a commonly applied stent coating composed of hydrophilic polymers that absorb water. This added surface water reduces friction and increases elasticity, rendering the stent easier to insert and theoretically more biocompatible. In vitro tests, however, have demonstrated hydrogel-coated stents to both reduce and increase encrustation and biofilm formation (Tunney et al, 1996; Desgrandchamps et al, 1997; Gorman et al, 1998).

Pentosan polysulfate (PPS), phosphorylcholine (PC) copolymer, and polyvinylpyrrolidone (PVP) are newer coatings that have been demonstrated to reduce inflammatory response, encrustation, and biofilm formation. Polyvinylpyrrolidone-iodine (PVP-I) complex modified polyurethane Tecoflex stents (Lubrizol, Wickliffe, OH) appear to be highly hydrophilic and to reduce encrustation deposits and adherence of *Pseudomonas aeruginosa* and *Staphylococcus aureus* by 80% to 86% in vitro tests (Khandekar and Doble, 2011). A diamond-like carbon (DLC) coating has been noted to render the stent surface ultrasMOOTH, thereby decreasing friction and improving biocompatibility. DLC-coated

polyurethane demonstrated significant resistance to biofilm formation and microbial adherence in in vitro and in vivo studies (Jones et al, 2006; Laube et al, 2007). Silicone coated with *Oxalobacter formigenes*-derived oxalate degrading enzymes demonstrated a modest reduction in encrustation in vivo compared with uncoated controls (Watterson et al, 2003a). Triclosan-eluting stents (Triumph [Boston Scientific, Marlborough, MA]) initially demonstrated a significant decrease in growth and survival of *P. mirabilis* in a rabbit study (Cadieux et al, 2006). The Triumph stent significantly reduced stent-related pain and urinary symptoms in short-term stented patients and reduced symptomatic UTI rate in long-term stented patients without, however, influencing biofilm formation, encrustation, or urine cultures (Cadieux et al, 2009; Mendez-Probst et al, 2012). A ketorolac-eluting stent (Lexington [Boston Scientific, Marlborough, MA]) was developed with the goal of reducing stent-induced pain symptoms. A prospective multicenter double-blind RCT evaluating the effect of Lexington stents reported no statistical difference in unplanned postoperative medical visits or pain perception. The authors did, however, demonstrate a significant reduction in the need for analgesia in the ketorolac-eluting stent group on post-URS day 2. Benefits of the stent were most evident in a subgroup of men and patients younger than 45 years (Krambeck et al, 2010). Although in vitro tests with heparin-coated stents did not show a significant benefit, in vivo tests demonstrated a significantly reduced encrustation rate. Tenke and Cauda noted that heparin-coated stents may remain indwelling for longer than 6 months and potentially up to 12 months, translating into an economic benefit (Riedl et al, 2002; Tenke et al, 2004; Cauda et al, 2008; Lange et al, 2009). Polyethylene glycol conjugated with 3,4-dihydroxyphenylalanine polymer, mPEG-DOPA₃, is a novel antifouling coating that demonstrated in vitro and in vivo resistance to bacterial attachment and biofilm formation. A cross-linked DOPA-anchored antifouling polymer was identified as the most resistant to *E. coli* adherence (Ko et al, 2008; Pechey et al, 2009). Sustained-release varnish containing chlorhexidine (CHX-SRV)-coated stents significantly reduce bacterial growth in vitro and in vivo with the initial 1% chlorhexidine concentration. The newly tested 2% concentration prolonged the inhibitory effect on bacterial growth up to 2 weeks (Shapur et al, 2012; Segev et al, 2013; Zelichenko et al, 2013).

Development of antibiotic coatings is still in a preliminary phase. Tests on rat models show promising results for rifampin-coated stents in combination with tigecycline and clarithromycin-coated stents in combination with systemic amikacin (Cirioni et al, 2011; Minardi et al, 2012).

Applying silver coatings on ureteral stents appears to be an effective strategy in reducing biofilm adherence without the risk of inducing resistance (Schierholz et al, 2002).

Stent Design

Simple variations to the initial DJ stent developed by Finney (Finney, 1978) include different biomaterials as discussed previously, different diameters and lengths, more or fewer side holes, and an open or closed tip.

The newly developed 3F Microstent (Percutaneous Systems, Palo Alto, CA) uses a film anchor as a proximal retaining mechanism. Once above the obstruction, the film anchor is deployed by retracting the integrated guidewire. Flow characteristics of the 3F Microstent are equivalent to those of a 4.7-Fr DJ stent and significantly better than those of a 3-Fr DJ stent (Lange et al, 2011). Because a smaller-caliber stent occupies less space in the ureter, stone passage may theoretically improve.

The grooved stent, initially invented by Finney in 1980 (U.S. patent 4,307,723), was demonstrated to have better extraluminal and total flow compared with a regular stent of equal size (Koleski et al, 2000). The Towers stent (Cook Medical, Bloomington, IN) and the LithoStent (Boston Scientific, Marlborough, MA) are two grooved stents still manufactured today.

The dual-lumen stent, developed with the goal of optimizing urinary drainage, significantly improved the flow in an ex vivo

obstructed ureter model compared with a single 7-Fr stent and had similar flow rates compared with two ipsilateral 7-Fr stents (Hafron et al, 2006). Insertion of a dual-lumen stent has a practical advantage over insertion of two ipsilateral stents because it can be inserted in one pass.

The Spirastent (Urosurge Medical, Coralville, IA), a DJ stent with helical metal ridges, was designed to obtain better flow and easier stone fragment passage by theoretically increasing the distance between ureter wall and stent. Although an in vitro study showed promising results, the stent appeared to allow less flow than the conventional DJ stent in an in vivo porcine model and was not successful in promoting enhanced stone clearance (Olweny et al, 2000; Stoller et al, 2000; Gerber et al, 2004).

The Open-Pass ureteral stent (Fossa Medical, Sandy Hook, CT) has 15 to 17 radially expanding baskets along its length and was developed for dilation of the ureter up to 20 Fr and stone fragment entrapment after SWL. Entrapped stone fragments are subsequently removed with the removal of the stent (L'Esperance et al, 2007).

Animal studies with a novel helical-cut Percuflex stent demonstrate the device to have flow characteristics and biocompatibility comparable to those of a conventional Percuflex stent. The touted advantage of the stent and its possible benefit in reducing stent-related symptoms depends on improved conformity to the ureter (Mucksavage et al, 2012).

Stents equipped with an antireflux valve mechanism at the intravesical portion of the stent demonstrate a significant decrease in reflux rate compared with a conventional DJ stent, resulting in less flank and bladder pain and thus improved patient comfort (Ecke et al, 2010; Ritter et al, 2012). Lumiaho reported that a 4-cm-long double-helix spiral stent made from biodegradable material allowed for adequate or improved flow compared with a conventional DJ stent in an in vivo porcine study. The absence of an intravesical coil prevented vesicoureteral reflux (Lumiaho et al, 2011).

The hypothesis that less or softer material in the bladder would result in fewer symptoms has influenced stent design toward variable diameter, dual durometer, and softer stents. Stents developed for use after endopyelotomy have a conventional 7-Fr proximal and distal coil and a broader body of 10 Fr or more. Tail stents or buoy stents were developed to prevent stent-related lower urinary tract symptoms and are composed of a 7-Fr or 10-Fr upper body that tapers down to a 3-Fr distal tail rather than a coil. Tail stents and buoy stents (10 Fr to 3 Fr) are reported to have significantly better drainage, reduced bladder inflammation, and reduced irritative bladder symptoms (Dunn et al, 2000; Krebs et al, 2009).

Reports on dual durometer stents, composed of a conventional upper body and a softer biomaterial at the distal segment, have not been proven to be consistently beneficial. Whereas Lingeman and colleagues reported significant reduction of stent-related symptoms with dual durometer stents, Davenport and Joshi could not identify significant differences between dual durometer and conventional DJ stents (Lennon et al, 1995; Joshi et al, 2005; Davenport et al, 2011; Kawahara et al, 2012a).

The Magnetip stent (Surgitek, Medical Engineering Company, Racine, WI) has been developed to avoid cystoscopic removal of the stent. It has a metallic bead at the distal tip and can be removed with a magnetic-tipped urethral catheter. Studies have demonstrated up to 100% successful retrieval in women and 75% to 97% in men (Macaluso et al, 1989; Taylor and McDougall, 2002).

Indications

Ureteral stent placement is most commonly performed to relieve ureteral obstruction. Intrinsic obstruction is typically caused by stones, tumors, or strictures, whereas extrinsic obstruction is often caused by compression by tumor, overlying vessels, retroperitoneal fibrosis, or lymphadenopathies. This relief of obstruction by stent placement can be temporary until more definitive treatment is performed or permanent if further definitive treatment is not feasible or desired.

Absolute and usually emergent indications for drainage of the kidney(s) are bilateral obstruction, unilateral obstruction

in the absence of a functional contralateral kidney, and ureteral obstruction with hydronephrosis and urinary infection or sepsis. Intractable renal colic that cannot be controlled by analgesia also requires urinary drainage by either a ureteral stent or nephrostomy placement.

Stent placement before or after treatment of urolithiasis has been a subject of controversy. A meta-analysis of the available literature demonstrated that stenting before SWL of upper urinary tract calculi may have a beneficial effect on the incidence of Steinstrasse after SWL. This result was, however, heavily influenced by one RCT with 400 participants with stones between 1.5 and 3.5 cm (Al-Awadi et al, 1999). There was no difference in need for auxiliary treatments between the two groups in the meta-analysis. Stenting has not conclusively demonstrated a beneficial effect on stone-free rates, and patients with a stent had more lower urinary tract symptoms (Ather et al, 2009; Shen et al, 2011a).

Current stone treatment guidelines from both the EAU and the AUA indicate that routine use of DJ stenting before SWL for kidney or ureteral stones does not improve stone-free rates. Although the guidelines advise against stent placement before an SWL-treatment regardless of stone size, it is still common practice and considered by many safer to place a ureteral stent in combination with SWL for a stone larger than 1.5 to 2 cm.

The requirement for routine stent placement after ureteroscopic lithotripsy (URSL) for stone treatment has also been widely debated. Findings from RCTs illustrating that stenting after uncomplicated URSL is not routinely required were published as early as 2001 (Denstedt et al, 2001). Three meta-analyses over the following decade all confirmed that routine stenting has no beneficial effect on stone-free rate or ureteral stricture formation. The procedure takes longer and costs more, especially combined with the cost of subsequent cystoscopic stent extraction. Quality of life appears to be better in the non-stented group (Shen et al, 2011b; Tang et al, 2011; Song et al, 2012a). The 2013 EAU stone guidelines advise that stenting is not routinely required after uncomplicated URSL (Türk et al, 2013). Stenting a ureter post-URSL is, on the other hand, still advised if there are sizeable residual fragments, in the presence of an anatomically or functionally solitary kidney, if the ureter has been balloon dilated, if the patient has a UTI, or if a complication such as bleeding or perforation has occurred. Even these commonly accepted indications for stent placement have been challenged in recent studies. A multicenter RCT demonstrated no benefit from stent placement after ureteric balloon-dilatation in an otherwise uncomplicated URSL. Stented patients had more discomfort, and there was no beneficial effect on postoperative pain, stone-free rate, or short- or long-term complication rates (Başeskioğlu et al, 2011).

A single retrospective study has evaluated the recommended indwelling time of ureteral stents post-URSL. The authors suggest that indwelling time shorter than 14 days was associated with fewer adverse effects compared with having the stent in for 15 days or longer (Shigemura et al, 2012). Because there are no RCTs in the current literature, there is not sufficient evidence to make conclusive recommendations on the indwelling time of a ureteral stent post-URSL. Common clinical practice is to remove a stent 1 to 2 weeks post-URSL if the patient is stone free or has small passable fragments on postoperative follow-up imaging.

Stenting as a preemptive maneuver before URS was first described and found beneficial as early as 1990 (Jones et al, 1990). Cetti and colleagues reported prestenenting to be useful in 8% of patients in a tertiary referral center (Cetti et al, 2011). Although no prospective RCTs have been performed to date, current literature suggests that placing a ureteral stent for 1 to 2 weeks after initial unsuccessful URSL leads to a higher success rate of secondary URSL (Rubenstein et al, 2007; Shields et al, 2009; Ji et al, 2012; Netsch et al, 2012). This passive dilative effect of an indwelling stent has also been demonstrated in the pediatric population (Hubert and Palmer, 2005; Corcoran et al, 2008). In addition, placement of a ureteral access sheath is easier in prestenented patients (Kawahara et al, 2012b).

Chu and coworkers demonstrated that stenting before a first attempt at URSL did not significantly improve stone-free rates; the authors reported, however, that preoperative stenting for stones larger than 1 cm was associated with decreased operative time, lower reoperative rates, and lower cost (Chu et al, 2011a, 2011b). **Whether or not a priori stenting before initial URSL should be routinely recommended for large impacted stones remains unclear because of a lack of qualitative trials.**

Routine placement of an internal stent after uncomplicated percutaneous nephrolithotomy (PCNL) with a low tract is not necessarily required. Stenting is, however, advised in the presence of residual stone burden in the kidney, migration of residual fragments to the ureter, extensive edema, perforation of the collecting system, or high tract placement with risk of hydrothorax; for performance of tubeless PCNL; or in the presence of persistent urinary leakage after nephrostomy tube removal.

The first RCT comparing **drainage modalities for pyonephrosis** was reported by Pearle and colleagues in 1998 and did not demonstrate superiority of stenting versus nephrostomy tube placement (Pearle et al, 1998). Mokhmalji concluded nephrostomy tube placement to be superior compared with internal stents, based mainly on more discomfort and pain in the stented group (Mokhmalji et al, 2001). Although Joshi reported significantly more irritative symptoms in stented patients compared with those with nephrostomy tubes, a patient preference for either could not be demonstrated (Joshi et al, 2001). The proportion of patients treated with percutaneous nephrostomy (PCN) for pyonephrosis in the United States decreased from 16% in 1999 to 11% in 2009. Recent literature suggests a preference for PCN tube for patients who have larger stones and are more acutely ill. These patients are also more likely to be admitted to an intensive care unit (Goldsmith et al, 2013; Sammon et al, 2013). **When considering the training and skill sets of most urologists, a “stent first where possible” policy has been suggested by Ramsey and associates (Ramsey et al, 2010).**

Stents are widely used in urologic reconstructive surgery for splinting the ureter. Stents have a dual role in this setting, the first being scaffolding the tissue to improve organized healing, and the second being to allow urine to flow unhindered past the operated field. Stents have shown usefulness in ureteral trauma treatment, ureteral realignment, pyeloplasty, ureteral reimplantation, uretero-ureterostomy, and other reconstructive procedures. A particularly important and well-studied postoperative use of ureteral stents is **after renal transplantation.** A recent meta-analysis in the renal transplant population demonstrated that **routine prophylactic stenting significantly reduces the incidence of major urologic complications (Wilson et al, 2013).** Removing the stent after 8 days as opposed to after 15 days reduces UTI rate (40% vs. 73%) and is more cost-effective (Parapiboon et al, 2012).

Stents are often placed **prophylactically before gynecologic, urologic, or abdominal surgery.** This facilitates identification of the ureter during surgery and theoretically may reduce iatrogenic ureteral trauma. Although such benefit has been suggested in gynecologic surgery, especially in patients with risk factors such as previous pelvic radiation or surgery, endometriosis, or pelvic inflammatory disease, a single-center RCT in a cohort of over 3000 patients showed **no significant difference in ureteral injury rate with or without prophylactic stenting (1.09% vs. 1.2%, $P = .774$).** It is, however, **easier to identify ureteric trauma with a stent in situ (Chou et al, 2009; Park et al, 2012).**

Several authors have reported on the use of stents in the **treatment of malignant pathology of the upper urinary tract** with, for instance, BCG or Mitomycin C. After intravesical instillation of the agent, vesicoureteral reflux may permit the substance to reach the upper urinary tract (Nonomura et al, 2000; Irie et al, 2002; Hayashida et al, 2004). Audenet suggests that BCG instillation in the upper urinary tract by single-J ureteral catheter, via reflux through DJ stent, or antegrade via a nephrostomy tube should be considered a first-line treatment for upper tract carcinoma in situ in patients who are not candidates for surgery (Audenet et al, 2013).

When a single ureteric stent is insufficient in relieving benign or malignant extrinsic ureteral compression, placing an additional ipsilateral stent has been reported to be successful in achieving adequate kidney drainage (Liu and Hrebinko, 1998; Rotariu et al, 2001; Elsamra et al, 2013). This technique has also been successfully applied in ureteral anastomotic strictures in renal transplant patients (Miyaoka et al, 2011).

Persistent urinary extravasation after blunt renal trauma can be treated by ureteral stent placement with high success rates (Matthews et al, 1997; Haas et al, 1998; Alsikafi et al, 2006; Long et al, 2013). Simultaneous bladder drainage is advised to maintain low intrarenal pressure and optimal drainage.

Technique

Stents can be placed using various techniques including endoscopic retrograde or antegrade placement or during open or laparoscopic surgery of the urinary tract. The following procedure describes a commonly used technique for retrograde endoscopic placement of a simple 7-Fr DJ stent of appropriate length without special design or coating and with a regular pusher, under cystoscopic and fluoroscopic guidance.

Antibiotic prophylaxis before endoscopic stent placement by means of oral fluoroquinolones is deemed appropriate and is recommended in AUA guidelines with level 1B evidence (Wolf et al, 2008).

Stent placement in males can be performed with the patient in a supine position with flexible cystoscopy or in lithotomy position when a rigid cystoscope is used. In females one can attempt flexible cystoscopy with the patient in a frog-leg position or perform rigid cystoscopy using the lithotomy position. Fluoroscopic guidance during the procedure to confirm the correct position of the guidewire and subsequently placed stent is advised. Ultrasound guidance can be used instead of fluoroscopy when placing a stent in a pregnant woman.

Ureteral stents are most commonly placed over a guidewire, and there is a vast array of available guidewires for this purpose. Hydrophilic nitinol guidewires have the optimal characteristics to easily overcome obstruction or follow the course of a tortuous ureter with a minimal risk of perforation. Stiffer wires such as Teflon-containing Benson wires provide higher resistance against bending when placing ureteral stents (Clayman et al, 2004; Liguori et al, 2008; Sarkissian et al, 2012; Torricelli et al, 2013).

Because stent diameter does not seem to influence stent symptoms, one should choose the largest fitting stent available for optimal drainage (Candela and Bellman, 1997; Erturk et al, 2003). In general, a 6-Fr or 7-Fr diameter stent is preferred.

After fluoroscopically confirming the position of the guidewire in the renal pelvis, the stent is advanced over the guidewire with a pusher under cystoscopic guidance. When the tip of the pusher is visualized at the bladder neck, the guidewire is retracted while the stent coils are fluoroscopically confirmed in the renal pelvis and the distal stent coil is cystoscopically confirmed in the bladder.

Alternatively, one can place a stent by primarily relying on fluoroscopic guidance. After placement of the guidewire in the renal pelvis, the cystoscope is removed and an 8-Fr to 10-Fr coaxial Amplatz dilator is advanced over the guidewire under fluoroscopic guidance until the 10-Fr component is at the urethral meatus. After removal of the 8-Fr component, the 10-Fr sheath will allow a 7-Fr stent to be passed through it over the guidewire while the stent is prevented from coiling in the bladder. Under fluoroscopic guidance, the stent is advanced with a pusher that has a radiopaque marker at the tip. The distal end of the stent is positioned by advancing the radiopaque marker under fluoroscopic guidance at the middle of the pubic symphysis in male patients and the lower border of the pubic symphysis in female patients. The 10-Fr sheath is removed and subsequently the guidewire, with fluoroscopic confirmation of the proximal stent coils in the renal pelvis and the distal loop coils in the bladder (Fig. 6-7).

Although usually performed with the patient under general anesthesia, stent placement with local anesthesia using lidocaine

Figure 6-7. A, Cystoscope in bladder plus guidewire in ureter. B, Stent placed in ureter through 10-Fr sheath (asterisk indicates radiopaque marker of pusher; arrow indicates 10-Fr sheath). C, Guidewire and 10-Fr sheath removed, distal stent section coiled in bladder.

jelly is feasible (Mark and Montgomery, 1996). Sivalingam describes that in compliant patients in whom difficult stent placement is not expected, in-office stent placement is feasible, is less costly, and has a low failure rate of approximately 9% (Sivalingam et al, 2013).

Complications

Stent Symptoms

Stent-associated symptoms can have a significant impact on patient quality of life. Hematuria, urgency, frequency, dysuria, and both bladder and flank pain are the most prevalent symptoms related to indwelling ureteral stents. Joshi and colleagues developed the ureteral stent symptom questionnaire (USSQ) to evaluate symptoms and impact on quality of life of ureteral stents. The authors reported quality of life to be influenced in 80% of stented patients. From an economic perspective, 58% of patients had reduced work capacity because of stent discomfort, and approximately half of the patients had sought medical professional help for stent-related symptoms (Joshi et al, 2003a, 2003b). Leibovici reported that 45% of patients had been unable to work for at least 2 days for a total of 435 work-days lost in 135 stented patients (Leibovici et al, 2005). A prospective cohort study reported that approximately one third of patients required early removal of ureteral stents because of stent discomfort (Ringel et al, 2000). Sexual dysfunction has been reported in 42% to 82% of male patients and 30% to 86% of female patients with an indwelling ureteral stent (Joshi et al, 2003b; Leibovici et al, 2005; Sighinolfi et al, 2007).

The pathophysiologic explanation for such stent-related symptoms is not yet fully understood. Irritation of the bladder mucosa and especially the trigone by the distal portion of the stent, reflux of urine, and smooth muscle spasm are thought to contribute to stent-related symptoms (Miyaoka and Monga, 2009; Regan et al, 2009). Vesicoureteral reflux as measured on cystoureterogram has been reported in 56% to 62% of stented patients (Mosli et al, 1991; Yossepowitch et al, 2005). Fluoroscopic imaging in patients with an indwelling stent revealed positional changes of the stent in relation to standing, sitting, and bending, which may explain why physical activity can influence stent discomfort (Chew et al, 2007).

Positioning the proximal coil in the upper pole of the kidney in contrast to in the renal pelvis appears to be better tolerated by stented patients (Liatsikos et al, 2001). Several authors have reported that stents crossing the midline of the bladder have a significant and deleterious influence on associated discomfort. Choosing the

appropriate stent length may therefore aid in ameliorating stent symptoms (Rane et al, 2001; Al-Kandari et al, 2007; Ho et al, 2009, 2010; Giannarini et al, 2011a). Predictive parameters for ideal stent length have been studied extensively. The in vivo measurement of the ureter with a 5-Fr ureteric catheter is often assumed as the true ureteral length. Pilcher and Patel suggested a predictive model for ideal stent length based on patient height: shorter than 5 feet 10 inches, 22-cm stent; 5 feet 10 inches to 6 feet 4 inches, 24-cm stent; and taller than 6 feet 4 inches, 26-cm stent (Pilcher and Patel, 2002). This model has been adopted widely and has been both confirmed by many (Hruby et al, 2007; Ho et al, 2009) and also contested (Paick et al, 2005; Kawahara et al, 2012d; Novaes et al, 2013; Shrewsbury et al, 2013). Paick and colleagues suggested that straight linear measurement from ureteropelvic junction to vesico-ureteric junction on preoperative intravenous pyelography correlated better with the actual ureteric length than the patient's height (Paick et al, 2005). Postmortem measurement of ureteric length could not identify a significant correlation with any anthropomorphic measurement (Novaes et al, 2013). Recent reports demonstrate actual ureteric length to correlate better with computed tomography (CT)-measured length than with any other imaging-based or anthropomorphic measurement (Kawahara et al, 2012d; Shrewsbury et al, 2013). Ideal stent length for children has been formulated as "child's age + 10" cm (Resnick et al, 2007).

Pharmacologic agent and altered stent design have been extensively studied in attempts to reduce stent-related symptoms. Meta-analysis of four RCTs with a total of 341 patients that assessed the efficacy of α -blockers with the USSQ has demonstrated that the use of α -blockers significantly reduces urinary symptoms and pain and significantly improves general health (Yakoubi et al, 2011). The use of α -blocker medications to mitigate stent discomfort has been recommended by EAU guidelines (Türk et al, 2013). Solifenacin and tolterodine can significantly reduce irritative urinary tract symptoms and pain symptoms with a very low complication rate (Park et al, 2009; Lee et al, 2013). The combination of tamsulosin and solifenacin appears to significantly improve stent-related irritative and obstructive symptoms compared with monotherapy with either agent alone (Lim et al, 2011). Intravesical instillation with ketorolac seems to have a short-lived but significant beneficial effect on postoperative stent-related pain (Beiko et al, 2004). Periureteral injection of botulinum toxin A has been demonstrated to safely reduce stent-related pain and need for narcotic pain medication up to 1 week after stent placement (Gupta et al, 2010). Injection of ropivacaine in proximity to the ureteric orifice and at the bladder neck demonstrated a trend toward decreased postoperative pain and voiding symptoms when

assessed in a small RCT (Sur et al, 2008). Appropriate stent position with the distal coil not crossing over the midline of the bladder appeared to have more effect on stent-related symptoms than α -blockers or anticholinergics in a prospective RCT (Lee et al, 2010).

Stent Migration

Despite the self-retaining design of DJ ureteral stents, distal migration into the bladder or proximal into the ureter is possible. Proximal stent migration into the ureter has been reported to occur in 1% to 8% of patients. This can largely be prevented by choosing a sufficiently long stent and having an adequate loop both in the renal pelvis and in the bladder (Slaton and Kropp, 1996; Richter et al, 2000; Breau and Norman, 2001). A proximally migrated stent can be retrieved ureteroscopically (Bagley and Huffman, 1991). The use of toothed graspers, grasping or coaxial cannulation of the stent with a basket, and a dilation balloon have been reported to aid in the retrieval of proximally migrated stents (Chin and Denstedt, 1992; Livadas et al, 2007; Meeks et al, 2008). Migration of the stent into the bladder can be treated by stent exchange.

Urinary Tract Infection

Ureteral stents are inherently subject to bacterial colonization and therefore represent a source of UTI. Short-term ureteral stent placement (3 weeks) in a cohort of 209 children after ureteral reimplantation eventuated in UTI in only 4.8% of patients. Asymptomatic bacteriuria was reported in an additional 6.5% of patients, whereas almost half of the stents were colonized with bacteria (Uvin et al, 2011). **In chronically stented patients, bacterial colonization reaches 100% (Riedl et al, 1999).** Indwelling time, female sex, diabetes, and chronic kidney disease are factors influencing colonization of ureteral stents (Kehinde et al, 2002). A negative urine culture has low predictive value for stent bacterial colonization (Kehinde et al, 2004; Rahman et al, 2012). Routine screening for bacteriuria and treatment of asymptomatic bacteriuria is not recommended. **Antibiotics are recommended only in instances of symptomatic UTI and appear not to have a role in long-term prophylaxis.** A small RCT with 95 patients demonstrated that continuous low-dose antibiotic treatment during the indwelling time of ureteral stents does not influence the incidence or severity of stent-related symptoms or UTIs (Moltzahn et al, 2013).

Encrustation

Minor encrustation on stent surfaces is often present and usually does not result in stent blockage or resistance at stent removal. More extensive and clinically significant encrustation can be a very challenging complication and often arises from a forgotten or retained stent. Removal of encrusted stents requires endourologic experience and, depending on the extent of encrustations, may include multiple interventions. Failure to acknowledge the presence of and render treatment for an encrusted stent can lead to significant renal functional impairment including renal unit loss and in rare instances mortality (Singh et al, 2005; Aron et al, 2006).

The duration of indwelling time of ureteral stents is the most important risk factor for development of encrustation. Encrustation has been reported to occur in 9.2% to 26.8% of stents indwelling for less than 6 weeks, in 47.5% to 56.9% of stents indwelling 6 to 12 weeks, and in approximately 75% of stents indwelling longer than 12 weeks (el-Faqih et al, 1991; Kawahara et al, 2012c). Kawahara and coworkers observed that **stents smaller than 6 Fr were significantly more likely to encrust than stents 7 Fr or larger.** The authors reported complete obstruction in 8.6% of stents after more than 12 weeks, and 1% of stents required additional treatments to facilitate stent removal (Kawahara et al, 2012c). Additional risk factors for stent encrustation include pregnancy, UTI or uropes- sis, history of stone disease, metabolic or congenital abnormalities,

urinary diversions, and chronic renal failure (Robert et al, 1997; Vanderbrink et al, 2008; Ahallal et al, 2010). Calcium oxalate appears to be the major component of stent encrustation in the absence of UTI, pH values below 5.5, and hyperuricosuria (Robert et al, 1997; Grases et al, 2001).

Because indwelling time is the most important risk factor for encrustation, **timely stent removal or exchange is the most important preventive measure.** Most stent manufacturers recommend stent removal or exchange within 4 months of placement. In patients with additional risk factors for encrustation, a 6- to 8-week interval is recommended (Aravantinos et al, 2006). Pregnant patients are especially prone to stent encrustation, and stent exchange is suggested every 4 to 6 weeks in this population (Denstedt and Razvi, 1992).

Encrustation and inability to extract a stent are usually diagnosed in an office setting at a trial of stent removal. Applying excessive force to achieve stent extraction is not recommended, to avoid the risk of inflicting ureteral damage, avulsion, or stent fragmentation. Adequate cross-sectional imaging to assess the extent of encrustation is assistive in developing a treatment strategy because conventional x-ray examination may underestimate the extent of encrustation. Mistry and coworkers reported on the placement of an additional stent for 1 to 2 weeks adjacent to mildly encrusted stents, facilitating a second extraction attempt. The authors hypothesize that friction between the two stents might disrupt the encrustation in addition to the beneficial effect of ureteral dilation (Mistry et al, 2013).

Several authors have created an algorithm for the treatment of encrusted stents involving SWL, URS, cystolitholapaxy, and PCNL. One to six multiple sequential procedures are often necessary to successfully remove the encrusted stent (Borboroglu and Kane, 2000; Singh et al, 2001; Lam and Gupta, 2002; Bultitude et al, 2003; Aravantinos et al, 2006; Weedon et al, 2011). The multitude of different algorithms reflects the lack of consensus on optimal treatment. In general, the site and level of encrustation burden guide the specific approach.

Forgotten or Neglected Stents

The forgotten or neglected stent is a multifactorial problem that originates from both poor patient compliance and health system issues related to patient follow-up. The surgeon responsible for stent insertion is also accountable for its timely removal.

The cost of forgetting a stent, including radiologic investigations, medical treatment, invasive and noninvasive interventions, and hospital stay is on average sevenfold higher than the cost of cystoscopic timely removal (Sancaktutar et al, 2012).

Divakaruni and colleagues identified male patients and uninsured patients to be at higher risk of noncompliance with planned stent removal. When relying only on patient information and education, the authors reported a 16% forgotten stent rate (Divakaruni et al, 2013). In addition to patient education, several reminder mechanisms incorporated into patient follow-up protocols such as log books, card- or Web-based registries, computerized logs, and software that arranges stent change or removal and sends reminder e-mails to patient and physician have been proposed to prevent the forgotten stent scenario from occurring, with variable effectiveness. None of these preventive mechanisms can completely eliminate the retained stent issue (Monga et al, 1995; McCahy and Ramsden, 1996; Ather et al, 2000; Lynch et al, 2007; Thomas et al, 2007; Tang et al, 2008; Withington et al, 2013).

Forgotten stents can develop severe encrustation, as previously described. In the presence of a large encrustation burden, nuclear imaging to quantify the renal function of the affected kidney is advised for planning stent removal. If split renal function shows insufficient contribution of the stented kidney, nephrectomy may be the most appropriate course of action.

Forgotten ureteral stents account for the highest number of postoperative-related claims pertaining to urology that are closed with indemnity payment in the United Kingdom (Osman and Collins, 2011).

UPPER URINARY TRACT: NEPHROSTOMY TUBE

Historic Note

Thomas Hillier reported on the first PCN for the drainage of a hydronephrotic kidney in a 4-year old boy in 1865 (Hillier, 1865). Goodwin described PCN to drain an obstructed kidney in 16 patients almost a century later (Goodwin et al, 1955). Fernström's report on the first percutaneous stone extraction in 1976 initiated the PCNL era, enhancing popularity of the percutaneous access and drainage of the kidney (Fernström and Johansson, 1976). The early literature review, pooling data of 516 PCN insertions, reported a success rate of 90%, major complication rate of 4%, and minor complication rate of 15% (Stables et al, 1978).

Available Materials and Nephrostomy Tube Design

Similar to ureteral stents, an ideal nephrostomy tube is biocompatible; has excellent flow characteristics; is easy to insert; resists infection, encrustation, and dislodgement; and does not induce symptoms.

The pigtail and balloon catheter are probably the most commonly used tube designs. In general, pigtail catheters are smaller than other nephrostomy tubes and are very useful for drainage of clear fluids but are often insufficient in the presence of gross hematuria or thick pus. Councill catheters are particularly useful because they can be inserted or exchanged over a guidewire without losing access to the kidney. Malecot and Pezzar nephrostomies have the advantage of a larger lumen because of their lack of retention balloon tubing. Re-entry catheters are designed to permit nephrostomy drainage while ensuring access to the ureter, should this be necessary. A tamponade (Kaye) catheter can be of specific use in instances of postoperative bleeding (Paul et al, 2003). Although small-bore catheters (smaller than 18 Fr) are less painful and better tolerated than large-bore catheters (larger than 18 Fr) (Maheshwari et al, 2000; Pietrow et al, 2003; Desai et al, 2004), overall complication rate and bleeding incidence after PCNL may be lower with a large-bore catheter (Cormio et al, 2013). Currently the placement of a 16-Fr to 18-Fr nephrostomy tube is common practice in non-tubeless PCNL.

Canales and colleagues compared a pigtail stent, a Malecot catheter, a catheter with a symmetrical balloon, and a catheter with an eccentric balloon in an artificial kidney model in an effort to identify the best tube design for nephrostomy placement after PCNL. The catheter with a symmetrical balloon had significantly better flow with water and higher-viscosity fluid and better retention strength compared with the other catheters (Canales et al, 2005) (Fig. 6-8).

Indications

When upper urinary tract drainage is desired and retrograde ureteral stent placement is not successful or feasible, PCN tube placement

is considered the procedure of choice. Advantages of PCN drainage include the placement and exchange of the tube under local anesthesia and the belief that a nephrostomy tube offers better flow characteristics. Anesthesia may not be an option in ill patients with acute renal failure or sepsis with hemodynamic instability. Because stent placement under local anesthesia appears to be feasible even in an office setting, this relative advantage may decline in the future (Sivalingam et al, 2013). In contrast to a DJ stent, the external drainage nephrostomy tube can be easily unblocked by gentle irrigation in the event of blockage.

Whereas patients with a stent have more discomfort from stent-related symptoms, the presence of a PCN tube has a negative influence on quality of life because of the external drainage characteristics. Overall quality of life, however, has not been demonstrated to be statistically different between the two groups (Joshi et al, 2001; Monsky et al, 2013). Although Monsky reported more minor complications and dislodgement in the PCN group resulting in more frequent exchanges, Song and colleagues reported a shorter interval of exchanges in the DJ stent group than in the PCN group (respectively, every 2.7 vs. 4.2 months). DJ stent placement was, however, less costly, and the procedure time was shorter (Song et al, 2012b; Monsky et al, 2013). Exchange frequency may have an economic and quality-of-life impact.

Acute decompression of obstructed pyonephrosis is a urologic emergency, and failure to achieve prompt drainage is related to a higher mortality risk (Borofsky et al, 2013). As previously discussed, there is not enough evidence from the current literature to demonstrate superiority of either nephrostomy or stent drainage in centers where both are readily available (Pearle et al, 1998; Mokhmali et al, 2001).

Multiple meta-analyses have consistently reported that tubeless PCNL is feasible and considered safe after an uncomplicated procedure without residual fragments, infection, bleeding, or collecting system perforation. In addition, a tubeless procedure reduces hospital stay, analgesia requirement, and time to return to normal activity (Yuan et al, 2011; Shen et al, 2012; Wang et al, 2012; Zhong et al, 2013).

Nephrostomy tubes may also be used to administer therapeutic drugs to the upper urinary tract. BCG or Mitomycin C for the treatment of upper urinary tract urothelial cancer as well as chemolytic agents to achieve stone dissolution are examples. Giannarini identified patients with carcinoma in situ of the upper urinary tract to benefit the most from upper tract BCG instillations (Giannarini et al, 2011b). If a nephrostomy tube is in place, it can be used to obtain a nephrostogram for diagnostic imaging.

In the treatment of malignant ureteric obstruction, drainage failure is significantly more prevalent in patients with ureteral stents compared with patients with a nephrostomy tube (Ku et al, 2004). Song suggested that patients with an obstruction larger than 3 cm are more likely to benefit from PCN than from DJ stent placement (Song et al, 2012b).

Figure 6-8. Nephrostomy tubes: types of nephrostomy catheters. A to C, Malecot, Pezzar, and Hulbert re-entry catheter. (Permission for use granted by Cook Medical, Bloomington, IN.)

How to obtain percutaneous access to the kidney is described in Chapter 8.

Complications

Hemorrhage, hematuria, clot colic, and UTIs are frequently reported minor complications of nephrostomy tube insertion. Sepsis occurs in 1.3% to 7% of patients, and trauma to adjacent organs caused by the procedure is uncommon. Transfusion rates of 2% to 4% have been reported as a result of venous or arterial bleeding. Venous bleeding is usually self-limiting. Persistent arterial bleeding or arteriovenous fistula is an uncommon but more severe complication that requires adequate imaging assessment and, if necessary, treatment with angioembolization. Thoracic complications (pneumothorax, hemothorax, hydrothorax, empyema) occur in 0.1% to 0.2% of nephrostomy tube placements. Late complications include tube dislodgement and blockage. Nephrostomy tube dislodgement is reported to occur in 2.5% of patients; this requires urgent assessment and, if necessary, tube replacement. A self-retaining catheter or retention suture fixation to the skin can aid in preventing tube dislodgement (Lewis and Patel, 2004; Wah et al, 2004; Hausegger and Portugaller, 2006; Rana et al, 2007; Ali et al, 2013).

Major complications are more common when procedures are performed during on-call hours, with lack of experienced staff implicated as a contributing factor (Lewis and Patel, 2004). Performing 10 to 20 PCNs per year improves success rate of the procedure (Lee et al, 1994).

Biofilm Formation on Urinary Tract Biomaterials

A *biofilm* is defined as a structured community of bacterial cells enclosed in a self-produced polymeric matrix and adherent to an inert or living surface.

Bacteria attempt to control their immediate environment by limiting exposure to harmful factors (waste products, antimicrobial agents, the host's immune response) while enhancing the exposure to trophic factors.

Despite continuing developmental efforts to achieve more biocompatible materials and surface coatings, indwelling catheters, stents, and nephrostomy tubes completely resistant to biofilm formation are as yet unavailable.

Biofilm-producing bacteria are the most important factor in inducing catheter- or stent-associated UTI and encrustation and the most common cause of stent failure (Ando et al, 2004; Chew et al, 2006; Ferrières et al, 2007).

Biofilm structures consist of three layers: (1) the **innermost layer**, attached to the surface of the biomaterial, which **functions as a linking film** for subsequent layers; (2) the **base film**, composed of microorganisms attached to the linking film; and (3) an **outer layer or surface film**, where microorganisms can be released (Tenke et al, 2012). The thickness of a biofilm can range from 3 to 490 μm and is composed of a few cell layers ranging from up to 400 cells deep (Ganderton et al, 1992).

The initial step in biofilm formation is the creation of a conditioning film on the surface of the biomaterial within minutes of insertion (Reid et al, 1995). This conditioning film is composed of **urinary components such as polysaccharides, Tamm-Horsfall proteins, electrolytes, and glycoproteins that adhere to the biomaterial surface**. The conditioning film alters the surface characteristics of the biomaterial, facilitating bacterial adhesions (Reid and Busscher, 1992). The initial bacterial adhesion is influenced by hydrophobic and electrostatic interactions, ionic forces, osmolality, and urinary pH and is **still reversible** (Gristina, 1987). The bacteria produce a matrix of exopolysaccharides and glycocalyx, rendering their adhesion irreversible. Eradication of the biofilm at this point is deemed impossible. Approximately 5% to 35% of the biofilm consists of bacterial microcolonies. The remainder is composed of interstitial spaces filled with fluid and water channels that allow transportation of nutrients and oxygen to the colonies (Tenke et al, 2012).

Resistance to antimicrobial treatment of bacterial biofilm infections is multifactorial:

1. **Quorum sensing** is a bacterial communication process depending on population density. Diffusible signaling molecules allow bacterial colonies to react to their environment in a synchronized manner, regulating biofilm formation, virulence, and antibiotic resistance (Li and Nair, 2012; Bhardwaj et al, 2013).
2. **The polymicrobial nature of biofilm** increases antibacterial resistance. Bacteria contained in biofilm actively recruit other bacterial strains, resulting in biofilm consisting of up to six different strains. *E. coli*, *P. aeruginosa*, and *Enterococcus faecalis* are most frequently found in biofilm in the urinary tract. *P. mirabilis*, *E. faecalis*, and *S. aureus* have a stronger biofilm forming capacity (Holá et al, 2010).
3. **Persister cells**, contributing up to 1% to the entire biofilm, reside in a dormant state and do not grow, which enhances resistance to the usual antibiotic mechanism of action. They are often the cause of chronic infections (Wood et al, 2013).
4. Although antimicrobial agents may have the ability to penetrate into a biofilm, antimicrobial action is compromised by **waste accumulation and an altered microenvironment** (low pH, low PO_2 , high PCO_2 , low divalent cation and pyrimidine concentration, low hydration level) (del Pozo and Patel, 2007).

Urease-producing bacteria in biofilm, such as *P. mirabilis*, *Proteus vulgaris*, and *Providencia rettgeri*, are able to raise the urinary pH to an alkaline level at which calcium and magnesium phosphates (hydroxyapatite and struvite) crystallize, deposit onto catheter or stent surfaces, and are incorporated into the organic matrix, creating encrustation (Broomfield et al, 2009). Canales and colleagues demonstrated that components of the conditioning film, α_1 -antitrypsin, Ig kappa, IgH G₁, and histone H2B and H3A, were highly associated with stent encrustation (Canales et al, 2009).

The difficulty in preventing and treating biofilm and biofilm-induced infections is the consequence of the complexity of biofilm

KEY POINTS

- The routine use of coated catheters for short-term catheterization is not recommended.
- Screening for asymptomatic bacteriuria in patients with an indwelling catheter or ureteral stent should not be performed.
- Surrounding organ injury is the most significant complication of suprapubic catheter placement and has been reported to occur in less than 1% to 2.7% of procedures.
- Stent symptoms influence the quality of life in 80% of stented patients and reduce work capacity in 58%.
- α -Blockers and anticholinergic medications may be useful for modifying irritative and obstructive symptoms related to indwelling double-J stents.
- The indwelling time of a ureteral stent is the most important risk factor for encrustation.
- Metal and segmental stents such as Resonance, Memokath 051, Uventa, and Allium stents are useful in relieving extrinsic ureteric compression.
- Innovations in stent design and coatings are undergoing investigation with the desired goal of reducing stent-associated complications and symptoms.
- Tubeless PCNL is feasible and considered safe after an uncomplicated procedure without residual fragments, bleeding, infection, or collecting system perforation.
- Biofilm-producing bacteria are the most important factor in inducing catheter- or stent-associated urinary tract infection and encrustation and the most common cause of stent failure.
- Bacterial biofilm resistance to antimicrobial treatment is a result of multiple factors including quorum sensing, polymicrobial nature of biofilm, the presence of persister cells, and an altered microenvironment in the biofilm.

structure and the different mechanisms that compromise antibacterial mechanisms of action. Better understanding of basic processes and insights into biofilm formation and resistance mechanisms will guide the next generation of catheter and stent development and design in search of the ideal biomaterial and coating.

History of Endoscopy

Basic Equipment and Video-Endoscopic Systems

Cystourethroscopy

The development of rigid and flexible endoscopes in combination with their myriad ancillary equipment transformed many of the surgical specialties including urology. Management of bladder outlet obstruction, urothelial tumors, ureteral obstruction, and nephrolithiasis have all been revolutionized by endoscopic procedures. This chapter highlights major events in the development of modern endoscopes and indications for cystourethrography and ureteropyeloscopy along with patient preparation; techniques are then described in detail. Many of these principles are greatly expanded on in other sections of this book.

HISTORY OF ENDOSCOPY

The term *endoscope* is credited to the French urologist Antonin Jean Desormeaux in 1853; however, attempts to look inside the human body date back to antiquity (Natalin and Landman, 2009). Major progress occurred in 1806 when Philipp Bozzini developed the first “modern” endoscope (Engel, 2003). The Lichtleiter or “Light Conductor” used angled mirrors to conduct candlelight from a sharkskin-covered box into the body through aluminum tubing. The instrument was too large to be used on the genitourinary system. In 1853 Desormeaux introduced a similarly designed but smaller-profile endoscope with improved mirrors that used a kerosene lamp for illumination (Shah, 2002). Through this instrument he excised a urethral papilloma, becoming the first individual to perform a therapeutic endoscopic procedure.

Both Bozzini’s and Desormeaux’s endoscopes were severely hampered by their poor illumination and limited field of view. In 1877 Max Nitze designed a cystoscope that helped overcome both obstacles (Herr, 2006). He moved the source of illumination (water-cooled electric platinum filament) to the end of the instrument and used a series of optical lenses placed at precise distances along the length of a hollow, air-filled scope to conduct and magnify the image. In 1887 Nitze abandoned the platinum filament for Edison’s light bulb.

The development of the Amici prism in 1906 allowed cystoscopic images to be offset 90 degrees while maintaining correct image orientation, (Gow, 1998). No major developments occurred in cystoscope design until 1966, when Harold Hopkins introduced glass rods with only short gaps of air between. Hopkins was able to greatly improve light transmission while decreasing scope size, paving the way for contemporary rigid cystoscopes and the first rigid ureteroscope in 1979 (Lyon et al, 1979).

The development of flexible endoscopes was made possible by the advent of fiberoptics. In 1854 John Tyndall demonstrated that light could travel through a curved stream of water by internal reflection (Whewell et al, 1854). This finding led to molten glass being drawn into flexible, small-diameter fibers for light transmission. Further refinements in this process eventually led to the development of fiberoptics for medical use.

Upper Tract Endoscopy

Conclusions

Although still widely used, fiberoptics are fragile and have limited optical resolution. In 1970 Boyle and Smith developed the charge-coupled device (CCD), a sensor with the ability to convert photons to an electrical charge and ultimately a digital image (Samplaski and Jones, 2009). Traditionally these chips were housed within cameras attached to existing scopes. Over the last three decades, advancements in endoscope design led to the incorporation of the CCD chip within the distal tip. Introduced in 2005, the ACMI DCN-2010 flexible cystoscope was the first commercially available digital endoscope (Natalin et al, 2009). Compared with rod-lens and fiberoptic bundle systems, digital sensor technology offers improved image resolution and durability without the need for a separate light cable and camera (Quayle et al, 2005).

BASIC EQUIPMENT AND VIDEO-ENDOSCOPIC SYSTEMS

At minimum, cystourethroscopy requires irrigation fluid, a light source, and an endoscope. Typical irrigation fluids include sterile water, glycine, and normal saline. If electrocautery is needed, a solution free of electrolytes should be used.

A high-intensity xenon or halogen external light source is used to deliver white light to the endoscope through a fiberoptic cable. Some units include an automatic light-sensing feature that provides constant illumination by adjusting light output.

First introduced into urologic practice in 2007, narrow band imaging uses only blue (415 nm) and green (540 nm) wavelengths to image the urothelium (Bryan et al, 2008). These two wavelengths are strongly absorbed by hemoglobin, improving visibility of urothelial capillaries, small papillary lesions, and carcinoma in situ. A meta-analysis of eight studies including 1022 patients found that narrow band imaging improves accuracy of detection of noninvasive lesions, including carcinoma in situ (Zheng et al, 2012). The impact of narrow band imaging on tumor recurrence has not been prospectively evaluated.

In the absence of an endoscope camera the practitioner views the image directly through the optical eyepiece at the proximal end of the instrument. However, in most instances the image will be viewed on a monitor that is part of a dedicated video-endoscopic unit arranged in a fixed or mobile tower (Fig. 7-1). Video-endoscopic units have several advantages, including better visualization, enhanced patient safety and surgical training, decreased risk of bodily fluid exposure to the urologist, and improved operative ergonomics.

Traditional video-endoscopic systems consist of a light source, endoscope camera, image processor and recorder, and monitor. Newer digital units have eliminated the need for an external camera, allowing the light source and video cable to be incorporated into a single, built-in housing (Fig. 7-2). In the traditional system the endoscopic image is conveyed to the camera via a series of glass

Figure 7-1. Video-endoscopic unit consisting of a fixed tower, monitor, light source, image processor, video-recording device, and printer.

rods or fiberoptic bundles. The optical image is then converted to an electrical charge (voltage waveform) by the camera's CCD chip. The unit's video processor then converts the analog voltage waveform into a digital video signal that is sent to the monitor. In contrast, digital video-endoscopic systems have the CCD chip located at the distal end of the endoscope. The image is immediately converted into an electrical signal that is once again managed by the video processor without the need for internal optics and a CCD camera.

CYSTOURETHROSCOPY

Indications

Cystourethroscopy is one of the most common procedures in urology. Routinely performed in both the office and operating room setting, cystourethroscopy provides direct visualization of the urethra and bladder. The upper urinary tract may be evaluated fluoroscopically by ureteral catheterization with retrograde instillation of contrast material.

Indications for office-based cystourethroscopy are summarized in [Box 7-1](#). Most are for diagnostic purposes, but a limited number of therapeutic procedures may also be performed. One of the most frequent reasons to perform cystourethroscopy is for microscopic and gross hematuria. In addition to directly visualizing the lower urinary tract, cystourethroscopy permits collection of cytologic specimens and retrograde pyelography in patients who are not candidates for intravenous contrast.

Urothelial carcinoma surveillance is another routine indication for cystourethroscopy. Small urothelial lesions may be biopsied and fulgurated in the clinic. Upper tract surveillance may be accomplished by selective ureteral catheterization with retrograde

pyelography, upper tract washes for cytology, and brush biopsies for histologic evaluation.

Lower urinary tract complaints such as recurrent infections, obstructive and irritative voiding symptoms, and chronic pelvic pain may be worked up cystoscopically. In select patients, urethral strictures, bladder stones, and foreign bodies may be treated in the office. Ureteral stents can also be placed or exchanged in clinic with fluoroscopic assistance.

Equipment

Cystourethroscopes are manufactured in a variety of sizes expressed in French (Fr) gauge. **In the system devised by French instrument designer Joseph-Frédéric-Benoît Charrière (1803-1876), a 1-Fr instrument has a circumference of $\frac{1}{3}$ mm (Osborn and Baron, 2006).**

Cystourethroscopes are available in rigid and flexible models. Each has its own advantages and disadvantages. Rigid cystoscopes use the Hopkins rod-lens optical system, which provides improved optical clarity compared with the fiberoptic bundles used in flexible endoscopes. This is becoming less noticeable because of the increasing adoption of digital flexible cystourethroscopes. Visualization is also enhanced by the greater irrigant flow rate of rigid endoscopes. Rigid cystourethroscopes have larger working channels, allowing a wider array of instruments to be used. Their rigid design also makes them easier to control with one hand, freeing the surgeon's second hand to manipulate ancillary instruments.

In contrast, the smaller size of flexible cystourethroscopes improves patient comfort, making them ideal for office-based procedures. Endoscope passage does not require the patient to be in the frog-leg or lithotomy position. Their active tip deflection makes it easier to completely inspect the bladder and negotiate an elevated bladder neck or median lobe of the prostate.

Rigid Cystourethroscopes

Rigid cystourethroscopes are manufactured in sets consisting of an optical lens, bridge, sheath, and obturator ([Fig. 7-3](#)). Configurations differ by vendor ([Table 7-1](#)). Optical lenses come with tip angles ranging from 0 to 120 degrees. Visualization of the urethra is best performed with a 0- or 12-degree lens. A 25- or 30-degree lens is commonly used for therapeutic purposes. A 70- or 120-degree lens may be required to completely inspect the anterior and inferolateral walls, dome, and neck of the bladder.

The bridge connects the optical lens to the sheath. Diagnostic bridges do not have a working channel. Therapeutic bridges have one or two working channels. Patients with an elevated bladder neck, large median lobe of the prostate, or ureteroneocystostomy may require use of an Albarran bridge. This specialized bridge contains a lever that deflects wires and catheters passed through the working channel to facilitate ureteral orifice canalization ([Fig. 7-4](#)).

Cystourethroscope sheaths come in a variety of sizes. Most have markings indicating the size of the sheath and associated working channels ([Fig. 7-5](#)). Smaller sheaths (15 and 17 Fr) are ideal for diagnostic cystoscopy; the larger models are used for therapeutic procedures requiring improved irrigant flow and larger working channels. Each sheath has an associated obturator that blunts the distal end of the sheath for passage into the bladder without visual assistance. In most instances blind endoscope passage should be performed only in women.

Flexible Cystourethroscopes

Flexible cystourethroscopes range between 16 and 17 Fr. Models differ with regard to tip deflection, direction of view, field of view, working channel size, illumination, and optics ([Table 7-2](#)). Most models do not have an offset lens and provide a field of view of approximately 120 degrees. Tip deflection ranges from 120 to 210 degrees and is either intuitive (same direction as lever deflection) or counterintuitive (opposite direction of lever deflection). Irrigation and instrument passage occur through the same working

Figure 7-2. Traditional rod-lens optical system compared with digital sensor video-endoscopes. CCD, charge-coupled device. (Courtesy Olympus, Center Valley, PA.)

channel. Photodynamic and narrow band imaging capabilities are available in some models.

Flexible cystourethroscopes are available in fiberoptic and digital models. Digital scopes do not require focusing or white balancing. They are now available in high-definition (1920×1080 pixels) and standard-definition (720×480 pixels) models. An in vitro study compared the resolution, contrast evaluation, depth of field, color representation, and illumination of fiberoptic, standard-definition, and high-definition flexible cystoscopes (Lusch et al, 2013). All three scopes were manufactured by Olympus (Olympus, Center Valley, PA). Compared with the fiberoptic and standard-definition models, the high-definition scope had a significantly higher resolution and depth of field. The high-definition scope's resolution was five times greater and it had a 37% larger image than the standard-definition model. Color representation was only slightly better, and there was no difference in contrast evaluation among the three

models. Illumination was significantly better in the fiberoptic model compared with both digital cystoscopes.

A randomized study of 1022 flexible cystoscopy cases compared optics, performance, and durability of fiberoptic and standard-definition digital scopes (Okhunov et al, 2009). There was a trend toward improved mean surgeon optical ranking in favor of the digital scopes ($P = .076$). There was no difference in durability between the models. Only two cystoscopes required repair (0.2% incidence rate), and both were damaged when the endoscope was placed in a storage case rather than during use.

Data from an independent endoscope repair company found that flexible cystoscopes require less than one repair every 2 years (Canales et al, 2007). The most common repair was to the rubber overlying the distal flexible segment. Unlike flexible ureteroscopes, flexible cystourethroscopes are robust, likely making the optical mechanism a lesser determinant of scope durability.

BOX 7-1 Indications for Office-Based Cystourethroscopy**HEMATURIA**

Gross
Microscopic

MALIGNANCY

Urethral cancer
Bladder cancer
Atypical cytology
Upper tract transitional cell carcinoma surveillance

LOWER URINARY TRACT SYMPTOMS

Recurrent urinary tract infections
Obstructive voiding symptoms
Irritative voiding symptoms
Urinary incontinence
Chronic pelvic pain syndrome
Urethral stricture disease

MISCELLANEOUS

Trauma
Bladder abnormalities seen on imaging
Removal of foreign bodies and small bladder stones
Hematospermia
Obstructive azoospermia

Patient Preparation

Informed consent must be obtained before any cystoscopic procedure is performed. A urinalysis and urine culture, if indicated, should be completed before cystoscopy. All urinary tract infections must be treated, given the risk of bacteremia and sepsis after lower urinary tract manipulation.

The American Urological Association (AUA) Best Practice Policy Statement on antimicrobial prophylaxis does not recommend antibiotic administration for routine diagnostic

cystoscopy in the absence of patient-related risk factors (Box 7-2) (Wolf et al, 2008). Prophylaxis lasting less than 24 hours with either a fluoroquinolone or trimethoprim-sulfamethoxazole is recommended for therapeutic procedures. Second-line alternatives include an aminoglycoside with or without ampicillin, a first- or second-generation cephalosporin, or amoxicillin/clavulanate. This recommendation is largely based on a meta-analysis of 32 randomized controlled trials evaluating antimicrobial prophylaxis before transurethral resection of the prostate (TURP), which showed a decrease in bacteriuria, bacteremia, symptomatic urinary tract infection, and high-grade fever (Berry and Barratt, 2002). Similar trials have not been performed for minor cystoscopic procedures.

Before cystourethroscopy the skin is prepared with an antiseptic agent. Most commercially available agents contain iodophors or chlorhexidine gluconate in either an aqueous or alcohol-based solution. Both chlorhexidine gluconate and alcohol-based solutions can damage mucous membranes and therefore are not recommended for use on the genitalia. Aqueous-based iodophor-containing products such as Betadine are safe on all skin surfaces regardless of patient age.

After application of an antiseptic agent a lubricating gel is injected into the urethra of patients undergoing flexible cystourethroscopy. Either a plain or lidocaine gel may be used. A meta-analysis of four randomized trials involving 411 patients found that patients who received lidocaine gel were 1.7 times less likely

to experience moderate to severe pain during the procedure (Aaronson et al, 2009). However, only one of the four trials showed a statistical benefit to lidocaine gel, which is consistent with a larger meta-analysis involving 817 patients from nine randomized trials that showed no difference in procedure tolerance (Patel et al, 2008b).

BOX 7-2 Patient Risk Factors Requiring Antimicrobial Prophylaxis

Advanced age
Anatomic anomalies of the urinary tract
Chronic corticosteroid use
Colonized endogenous or exogenous material
Distant coexistent infection
Immunodeficiency
Poor nutritional status
Prolonged coexistent infection
Smoking

Other techniques have been employed to improve patient comfort during flexible cystourethroscopy. For the majority of men, the most uncomfortable part of the procedure is when the scope passes through the membranous urethra (Taghizadeh et al, 2006). A randomized trial was performed on 151 men undergoing flexible cystourethroscopy (Gunendran et al, 2008). Half of the subjects had the hydrostatic pressure of the irrigation solution increased by manual compression of the irrigation bag during passage of the scope through the membranous urethra. Gravity irrigation alone was used for the remaining patient. A significant improvement on an analog pain scale score was noted (1.38 vs. 3.00, $P < .001$) in the manual compression group.

The impact of being allowed to observe the procedure has also been evaluated. One hundred male patients undergoing flexible cystourethroscopy were randomized; half the subjects were allowed to observe the procedure on a video monitor whereas the remaining patients were not (Patel et al, 2007). Men who watched the procedure had significantly less pain on a 100-mm visual analog pain scale (14 vs. 23, $P = .02$). These findings were confirmed by another randomized study of 76 male patients (Soomro et al, 2011). Men in the observation group had less pain and lower postprocedure pulse rates. In contrast, a randomized study of 100 women undergoing office-based cystoscopy with a 17-Fr rigid scope found no difference in procedural pain (Patel et al, 2008a).

The potentially calming effect of music has also been examined. Seventy men undergoing flexible cystoscopy were randomized to either no music or classical music played during the procedure (Yeo et al, 2013). Patients listening to classical music had significantly less pain, greater satisfaction, lower postprocedure pulse rates, and lower systolic blood pressures.

Technique

Before insertion of the cystourethroscope, the external genitalia is inspected for cutaneous lesions and anatomic abnormalities. Mild meatal stenosis may be addressed with sequential metal dilators. Dilation should be performed to at least 2 Fr wider than the intended endoscope.

In women, rigid cystourethroscope insertion is safest using the sheath obturator. The scope will often need to be directed anteriorly as it is advanced into the bladder. Flexible cystourethroscopes can often be inserted into the bladder like a Foley catheter, with active deflection being used as needed.

In men, the penis is placed on maximal stretch to straighten the urethra. When a rigid cystourethroscope is being passed, the penis is typically grasped with all five digits of the surgeon's nondominant hand. With flexible cystourethroscopy the penis is pinched between the fourth and fifth digits of the nondominant hand at the corona while the thumb and index finger help advance and direct the scope into the urethra (Fig. 7-6). In morbidly obese

Figure 7-6. During flexible cystoscopy the distal penis is grasped between the surgeon's third and fourth fingers and placed on stretch while the thumb and index finger advance the cystoscope into the urethral meatus.

patients it is often easier to lay the scope down, retract the pannus with the nondominant hand, and direct the tip of the flexible scope into urethra like a Foley catheter. Once in the mid-penile urethra the scope is placed in the dominant hand and advanced as usual.

The penis should be angled 45 to 90 degrees relative to the abdominal wall while the scope is passed through the anterior urethra. Once beyond the membranous urethra the cystoscope is directed anteriorly to enter the bladder. With flexible cystoscopes this is accomplished by active upward deflection and with rigid cystoscopes by dropping the distal end of the scope toward the operative table.

The lower urinary tract is systematically evaluated under maximal irrigation as the scope is advanced. The penile and bulbar urethra are inspected for strictures. The periurethral glands of Littre should be noted as they drain into the urethra dorsally. Patients, in particular young men, should be encouraged to relax as much as possible as the scope is advanced through the membranous urethra. Once the scope is in the prostatic urethra, the verumontanum and utricle are identified posteriorly. The length of the posterior urethra is measured and the size of the prostatic lobes is evaluated.

Once the scope is in the bladder, the mucosa is carefully inspected. Rigid cystoscopy is usually begun with a 25- or 30-degree lens. The floor of the bladder and trigone are surveyed. The number, location, and configuration of the ureteral orifices are noted. Efflux from each ureter should be observed for the presence of gross blood. The remainder of the bladder is inspected for stones, trabeculation, cellulules, diverticula, erythematous patches, and papillary and sessile lesions. Visualization of the lateral walls is accomplished by rotating the cystoscope while keeping the camera orientation fixed. The dome and anterior and posterolateral walls are inspected with a 70- or 120-degree lens. After completion of the procedure, the bladder is emptied and the endoscope withdrawn. If a Foley catheter is to be placed after the procedure, it is best to leave the bladder at least partially full before removing the cystoscope.

Special Circumstances

Suprapubic Cystostomy

The indications for cystoscopy in patients with suprapubic cystostomy tubes are the same as for those without chronic indwelling

catheters. Nevertheless, these individuals are at increased risk of infection, bladder calculi, and bladder cancer (Subramonian et al, 2004; Welk et al, 2013; El Masri et al, 2014). At present there are no level 1 data showing improved survival in patients with long-term indwelling catheters undergoing surveillance cystoscopy. However, in patients with catheters for more than 5 to 10 years, surveillance cystoscopy is a common practice.

Cystoscopic evaluation may be performed transurethrally or via the patient's suprapubic tract. However, many patients with long-term suprapubic tubes have urethral stricture disease, making the suprapubic tract the only feasible route to the bladder. Every effort should be made to avoid endoscopy through a suprapubic tract until it has had time to mature, which usually takes several weeks from the time of creation. If endoscopy of an immature tract is required, it is advisable to place a wire through the tract into the bladder to guide the endoscope. This technique is also helpful in morbidly obese patients with long, often tortuous tracts.

Ureteral access is often challenging during rigid cystoscopy because of the acute angle required to cannulate the ureteral orifice via the cystostomy tract. Use of angled catheters such as the Kumpe Catheter (Cook Medical, Bloomington, IN) or an Albarran deflector may facilitate ureteral access. Use of a flexible cystoscope will often overcome these problems. Alternatively, patients with low-grade urethral strictures may be able to accommodate transurethral passage of a semirigid ureteroscope facilitating standard ureteral access. Lastly, the ureteral orifices may be difficult to identify because of edema caused by the chronic suprapubic tube. Administering intravenous indigo carmine or methylene blue early in the procedure may help visualize the ureteral orifices.

Continent Urinary Diversions

There are two general classes of continent urinary diversions after cystectomy. Orthotopic urinary diversions are anastomosed to the urethra and rely on the striated urinary sphincter to maintain continence. Continent cutaneous reservoirs use a catheterizable channel anastomosed to the diversion and anterior abdominal wall. The catheterizable channel may be composed of the appendix (Mitrofanoff), tapered or imbricated terminal ileum and ileocecal valve, or an intussuscepted nipple valve.

Before any endoscopic procedure involving a continent urinary diversion, it is imperative to obtain the operative note. It is important to know the bowel segment used, type and location of the ureteroenteric anastomoses, continence mechanism employed, and whether an afferent limb was created.

Transurethral access to orthotopic diversions is often straightforward and can be accomplished using a rigid cystoscope. If a contracture is noted at the urethral anastomosis and the patient does not have outlet obstruction, then it is advisable to use the smallest scope possible rather than dilate or incise the stricture because of the risk of worsening urinary incontinence.

Diagnostic procedures on continent cutaneous reservoirs are best accomplished with a flexible cystoscope through the catheterizable channel. Therapeutic procedures should be performed percutaneously, given that continence mechanisms are often fragile and excess manipulation may result in either stomal stenosis or urinary incontinence (L'Esperance et al, 2004). Preoperative computed tomography (CT) or intraoperative ultrasound should be used to minimize the risk of bowel injury during percutaneous access.

Once within the diversion, visualization is often challenging because of mucus, mucosal folds, bowel peristalsis, and, if present, tortuous afferent limb. Begin by irrigating out all of the mucus. Irrigation should then be used judiciously. Too little irrigation will make mucosal folds more prominent and impair visualization, but overdistending the diversion will prevent access to the afferent limb. Once again, ancillary techniques such as use of angled catheters and indigo carmine or methylene blue may be required.

KEY POINTS: CYSTOURETHROSCOPY

- Rigid cystourethrosopes are manufactured in sets consisting of an optical lens, a bridge, a sheath, and an obturator.
- Flexible cystourethrosopes are available in fiberoptic, standard-definition, and high-definition digital models.
- Cystourethroscope sizes are expressed using the French gauge system; 1 Fr is equal to $\frac{1}{3}$ mm in circumference.
- The smallest-diameter cystourethroscope that can be used to perform the procedure should be selected to decrease the risk of genitourinary tract trauma.
- Antimicrobial prophylaxis is not recommended for diagnostic cystourethrosopy unless patient risk factors are present.
- Increasing the hydrostatic pressure during scope passage and allowing men to observe the procedure have been prospectively shown to improve comfort during flexible cystourethrosopy.

UPPER TRACT ENDOSCOPY

Indications

Urolithiasis

The treatment of stones is the most common indication for ureteroscopy. Rigid ureteroscopy has long been the preferred treatment for distal ureteral stones. Shock wave lithotripsy (SWL) was favored for stones above the iliac vessels, because early results using rigid ureteroscopy for mid-ureteral and proximal ureteral calculi were discouraging. However, improvements in ureteroscopes and working instruments, the use of the holmium laser, and greater use of the flexible ureteroscope have significantly improved stone-free rates after ureteroscopic treatment of stones above the iliac vessels.

Although SWL remains a valuable treatment option for renal and ureteral stones, there are certain clinical situations in which, because of SWL limitations, ureteroscopy is preferred. Frequent causes of shock wave lithotripsy failure include radiolucent or difficult-to-visualize calculi, concomitant obstruction distal to the calculus, poor passage of lower pole fragments, and failure to fragment dense calculi. In addition, morbidly obese patients who exceed the weight limit or focal length of many shock wave lithotripters can be successfully treated ureteroscopically.

Percutaneous nephrostolithotomy is the treatment of choice for large (>2 cm) intrarenal calculi. However, in patients with significant comorbidities that would make percutaneous nephrostolithotomy dangerous, flexible ureteroscopy has been successfully used. Two studies have reported stone-free rates of 91% and 93% for ureteroscopic treatment of patients with stones larger than 2 cm (Grasso et al, 1997; Breda et al, 2008).

Upper Urinary Tract Transitional Cell Carcinoma

The standard treatment for upper urinary tract transitional cell carcinoma is nephroureterectomy. However, with improvements in flexible ureteroscopic instrumentation and technique, there is increased use of endoscopic treatment of well-selected patients with upper urinary tract transitional cell carcinoma. Accordingly, the principles of endoscopic management of transitional cell carcinoma have been extended from the bladder to the upper urinary tract. With expansion of ureteroscopy for the diagnosis, ablation, and subsequent surveillance phases of upper tract transitional cell carcinoma management, this is becoming a frequent indication for ureteroscopy.

Many patients treated ureteroscopically for upper urinary tract transitional cell carcinoma are those in whom nephroureterectomy would be dangerous: patients with a solitary kidney, renal insufficiency, bilateral upper tract transitional cell carcinoma, or significant medical comorbidities. There is also increasing use of ureteroscopic treatment for patients with low-grade, low-volume

disease. Endoscopic management of these patients has proven to be a reasonable option, without compromise of patient survival (Cutress et al, 2012b; Grasso et al, 2012). Larger tumors can be difficult to fully ablate in one session. Percutaneous nephroscopy and electroresection have been used and permit resection of large amounts of tumor (Irwin et al, 2010; Cutress et al, 2012a). However, the ureteroscopic approach may be preferred because it avoids the risk of seeding the percutaneous tract and retroperitoneum with tumor. The risk of tract seeding is small, but it has been reported (Sharma et al, 1994; Sengupta and Harewood, 1998).

Ureteropelvic Junction Obstruction and Ureteral Stricture

Despite the growing and successful use of laparoscopic ureteropyeloplasty, endopyelotomy is still a reasonable choice for the management of select patients with ureteropelvic junction (UPJ) obstruction. This can be performed percutaneously, ureteroscopically, or with the Acucise (Applied Medical Resources, Laguna Hills, CA) cutting balloon catheter device. The advantages of the ureteroscopic approach include the ability to control the length and depth of the incision under direct vision, the avoidance of percutaneous renal access, and the ability to perform the procedure in an outpatient setting.

There are two situations in which ureteroscopic endopyelotomy may not be the preferred approach. Patients with concomitant renal calculi should be treated via a percutaneous approach to allow simultaneous removal of the calculi and endopyelotomy. Also, several studies have demonstrated a decreased success rate with endopyelotomy in patients who have vessels crossing at the UPJ (Van Cangh et al, 1994; Bagley et al, 1995; Conlin et al, 1998; Tawfik et al, 1999). **It may be best to limit ureteroscopic endopyelotomy to those patients without known crossing vessels, and treat those with crossing vessels with laparoscopic ureteropyeloplasty.**

Patients with ureteral strictures can also be managed from a ureteroscopic approach. The technique is nearly identical to the ureteroscopic endopyelotomy technique. Endoureterotomy will be less successful in patients with ureteral strictures longer than 1.5 cm, allograft ureters, previously irradiated ureters, ureters draining poorly functioning kidneys, and ureteral-enteral anastomotic strictures (Wolf et al, 1997). Ureteroscopic incision of short ureteral strictures in otherwise healthy ureters is a reasonably successful treatment option.

Other Indications for Ureteroscopy

Diagnostic flexible ureteroscopy can be performed in patients with persistent positive cytology, filling defects, hematuria, and recurrent urinary tract infections localized to a single renal unit. With the miniaturization of flexible ureteroscopes, the safety of flexible ureteroscopy has increased significantly. Rather than relying on ureteropyelography alone, we can now safely and easily perform diagnostic ureteroscopy.

Ureteroscopy has also been used for removal of foreign bodies including suture, proximally migrated ureteral stents, balloon catheters, and other fractured working instruments. The three-pronged grasping forceps are ideally suited for grasping and removing these foreign bodies.

Benign essential hematuria can be diagnosed and treated with flexible ureteroscopy. This condition is defined as unilateral gross hematuria for which there is no radiographically defined cause (Lano et al, 1979; Bagley et al, 1987). These patients frequently have had studies including excretory urography, renal sonography, and/or arteriography. Flexible ureteroscopic inspection of the kidney involved usually results in diagnosis and successful treatment. The most common finding in patients with benign essential hematuria is a small hemangioma, which can often be fulgurated. Other endoscopic findings in patients with benign essential hematuria include small venous ruptures, papillary tumors, varices, and calculi (Dooley and Pietrow, 2004).

Equipment

Semirigid Ureteroscopes

Performance of successful ureteroscopy requires a variety of instrumentation—most important, appropriate and modern ureteroscopes. Although larger rod-lens rigid ureteroscopes are still available in some operating rooms, the smaller-diameter fiberoptic ureteroscopes are less traumatic, less often require ureteral dilation, and are equally effective.

Semirigid ureteroscopes are smaller in diameter because of the incorporation of fiberoptics into their construction. Fiber optic bundles are created from molten glass that has been pulled into small-diameter fibers. Each individual glass fiber is “cladded” with a second layer of glass of a different refractive index. This cladding improves the internal reflection, light transmission, and durability of the fiberoptic bundle. The meshlike appearance of the image from fiberoptic image bundles is caused by the lack of light transmission through this cladding. These fibers uniformly transmit light from one end of the fiber to the other proportional to the light input. The glass fibers of a fiberoptic bundle can be arranged randomly or in a precise orientation with identical location at each end of the fiber (i.e., coherent). When the fibers are grouped randomly, such as those within the light bundle, they provide excellent light transmission for illumination, but no image. When the fibers are arranged in a coherent fashion, the light from each fiber within the bundle will coalesce to transmit images.

Small lenses are attached to the proximal and distal ends of the image bundle to create a telescope. By controlling the number of fibers in the bundle, and the type and orientation of the lenses, the manufacturers can determine the degree of image magnification, field of view, and focusing ability for different fiberoptic endoscopes. For example, by changing the axis of the lens at the distal tip of the image bundle, the angle of view of the ureteroscope can be changed to improve visibility of any working instruments passed out the working channel (Higashihara et al, 1990).

Improvements in image bundle construction have allowed closer packing of more fibers, resulting in improved images, smaller outer diameters, and larger working channels in both rigid and flexible ureteroscopes. Another design modification is the splitting of the light bundle distally into two points of light transmission (Conlin et al, 1997). This makes possible a more centrally placed working channel as well as better distribution of the light within the working field of view.

Current semirigid ureteroscopes typically have tip diameters of 7 Fr or smaller and working channels larger than 3 Fr. Semirigid ureteroscopes have either large single or two smaller individual working channels. **An advantage of the separate working channels is the ability to irrigate through one unrestricted channel while a working instrument occupies the other. Separate working channels also permit passage of a lithotripsy device through the separate channel to fracture a stone that cannot be disengaged from a basket in the other channel.** With a single channel, this can be difficult because of entanglement between the two working instruments.

Eyepieces are commonly “in line” with the ureteroscope, which allows easy introduction of the scope (Fig. 7-7). Offset eyepiece design makes possible a straight working channel for the use of more rigid working instruments such as rigid biopsy forceps or a pneumatic lithotripsy probe (Fig. 7-8). Increased availability and use of the holmium laser for ureteroscopic lithotripsy has decreased the need for ureteroscopes with offset eyepieces.

Figure 7-7. Semirigid ureteroscope with “in-line” eyepiece.

Figure 7-8. Semirigid ureteroscope with an offset eyepiece, which has a straight working channel permitting passage of rigid instruments.

Larger ureteroresectoscopes (11.5 Fr) can be useful for large distal ureteral tumor resection. Some surgeons also preferred using this instrument for ureteroscopic endopyelotomies (Thomas et al, 1996). Preoperative ureteral stenting will be necessary in this setting to allow passage of the larger-diameter ureteroresectoscope, especially to the UPJ.

Currently available semirigid ureteroscopes and their characteristics are listed in Table 7-3.

Flexible Ureteroscopes

The fundamental components of flexible ureteroscopes include the optical system, deflection mechanism, and working channel. The nondigital optical system consists of flexible fiberoptic image and light bundles. Improvements in the fiberoptic image bundles are discussed in the preceding section and are similar to those used in semirigid ureteroscopes.

The deflection mechanism is an integral part of every flexible ureteroscope. It permits complete maneuverability within the intrarenal collecting system (Bagley, 1989). The deflecting mechanism consists of control wires running down the length of the ureteroscope that are attached proximally to a manually operated lever mechanism. The control wires pass through movable metal rings to the distal end of the scope where they are fixed. Moving the lever up or down pulls the control wire through these rings and deflects the tip. When the tip moves in the same direction as the lever, the deflection is said to be “intuitive” (i.e., down is down and up is up). Most modern flexible ureteroscopes allow both up and down deflection in a single plane (Grasso and Bagley, 1994). The plane of deflection is designated by the reticle, seen as a notch within the field of view of the ureteroscope (Fig. 7-9). When the flexible ureteroscope is maneuvered, it must be rotated to align the plane of deflection with the intended target. The active deflection mechanism eventually wears out with repeated use, necessitating repair or replacement of the ureteroscope. Improvements in the construction of the deflecting mechanism with each new generation of flexible ureteroscopes continue to improve durability.

Most current flexible ureteroscopes permit deflection of 180 degrees or more. The amount of deflection necessary to reach the lower pole of the kidney varies among patients. One group of investigators measured ureteroinfundibular angle (between the major axis of the ureter and the lower pole infundibulum) in 30 patients. They determined an average angle of 140 degrees with a maximum of 175 degrees (Bagley and Rittenberg, 1987). Active deflection of the ureteroscope of 180 degrees should allow visualization of the lower pole in most patients. However, reaching into the lower pole calyx with the tip of the ureteroscope in a fashion that allows endoscopic work to be done can still be challenging.

Active deflection occurs only at the distal tip of the ureteroscope, and the deflected segment may not be long enough to reach the lower pole calyx. Most flexible ureteroscopes have a more flexible segment of the ureteroscope because of a weakness in the durometer of the sheath, located just proximal to the point of active deflection. This secondary, passive deflection mechanism addresses the difficulty of reaching the lower pole in some patients. By passive bending of the tip of the ureteroscope off the superior margin of

the renal pelvis, the point of deflection is effectively moved more proximally on the ureteroscope, thereby extending the tip of the ureteroscope. When passive deflection is used, the lower pole calyx can be reached in the majority of patients. Many of the failures to reach the lower pole will occur in patients with significant hydronephrosis, which can limit the ability to engage passive secondary deflection.

To address the difficulties with ureteroscopic access to the lower pole, two innovations in ureteroscope deflection have been developed. These are active secondary deflection and exaggerated deflection. The first ureteroscope incorporating active secondary deflection, the DUR-8 Elite, was developed by Circon-ACMI, now part of Olympus (Center Valley, PA). In addition to active primary deflection of 185 degrees down and 175 degrees up, there is a second control lever for active secondary deflection of 165 degrees, which can be locked in place. Combining both primary and secondary deflection resulted in a maximum deflected angle of 234 degrees (Shvarts et al, 2004). This ureteroscope can assist the urologist to reach the lower pole even under conditions in which access with passive secondary deflection is not possible (Fig. 7-10). Locking the secondary deflection in place simplifies manipulation of the primary deflection within the lower pole calyx. The usefulness of active secondary deflection has been evaluated by Ankem and coworkers (Ankem et al, 2004). In a series of 54 patients, they found the dual deflecting DUR-8 Elite ureteroscope helpful in cases in which the single-deflection flexible instruments failed in accessing and treating upper urinary tract pathology. Despite these advantages, the DUR-8 Elite is no longer manufactured by Olympus, and there is currently no available flexible ureteroscope with active secondary deflection.

Karl Storz Endoscopy (Tuttlingen, Germany) introduced exaggerated deflection with their Flex-X model flexible ureteroscope (Johnson and Grasso, 2004). This modification of the deflection mechanism permits active primary deflection of greater than 300 degrees (Fig. 7-11). When approaching the lower pole calyx, the deflected segment of the ureteroscope will effectively lengthen as it is deflected against the lower pole infundibulum. This improvement of the deflection mechanism results in easier lower pole access and improved deflection when working instruments are used.

All currently available flexible ureteroscopes have working channels of 3.6 Fr diameter. This allows use of instruments up to 3 Fr while still permitting adequate irrigation. When working instruments are used, higher pressure irrigation will be necessary to compensate for the effectively smaller irrigation channel (Bach et al, 2011). This higher pressure irrigation can be delivered using a pressurized irrigation bag, roller pump, or hand-held devices. The development of a dual channel flexible ureteroscope, the Cobra from Richard Wolf (Vernon Hills, IL), is an innovation that can improve irrigation through the ureteroscope. The dual 3.3 Fr channels will permit unimpeded irrigation through one channel while the working instrument occupies the other (Haberman et al, 2011). One may also use both channels for working instruments, such as a laser and a basket, but this is rarely necessary.

Digital Ureteroscopes

Digital flexible ureteroscopes have been developed and released by each of the three primary endoscope manufacturers. Like digital flexible cystoscopes described earlier in this chapter, these ureteroscopes integrate the endoscope, the digital camera, and the light source. A separate camera head is not needed because the scope has a digital camera chip (CCD or complementary metal-oxide semiconductor [CMOS]) mounted on its tip. Because these devices do not require a separate light cord or camera head, they are potentially less prone to damage and may have a prolonged life span.

Currently the digital flexible ureteroscopes available are larger diameter. One group of investigators performed a prospective comparison between digital and fiberoptic ureteroscopes to determine the influence of these larger-diameter digital scopes on patient outcomes. They found a higher use of ureteral access sheaths and related complications in those patients who underwent

ureteroscopy performed with a digital ureteroscope (Bach et al, 2012). In another analysis of the efficacy of digital and flexible ureteroscopes, investigators determined a statistically equivalent stone-free rate but a significantly shorter operative time in the digital group (Somani et al, 2013). This is presumed to be a result of the improved visibility of the digital ureteroscopes (Fig. 7-12). These digital ureteroscopes may advance future miniaturization, optimize digital resolution, and improve durability.

The specifications of currently available flexible ureteroscopes are detailed in Table 7-4.

Care and Sterilization

Rigid and especially flexible ureteroscopes are very delicate instruments and need to be handled accordingly. Any damage to the working channel, deflecting mechanism, or fibers within the image bundle can render the ureteroscope useless. One series reported that repairs of flexible ureteroscopes were necessary after only 3 to 13 hours of use (Afane et al, 2000). The repairs were usually caused by deterioration of the deflecting mechanism.

The working channels of flexible ureteroscopes are also easily damaged. This primarily occurs during passage of the small (200 μ) holmium laser fiber. When the fiber is introduced into a flexible ureteroscope that is even minimally deflected, the tip of the fiber may scrape the inner working channel. This can raise a small irregular area of the channel that will be more prone to damage.

Figure 7-9. Flexible ureteroscopic image showing the reticle (arrow), which designates the plane of deflection (dotted line).

With each future pass of a laser fiber, the working channel can be increasingly damaged and ultimately perforated by the fiber. Once perforated, sterilization of the flexible ureteroscope will result in fluid damage to the imaging system of the scope, making the scope unusable. **Firing the fiber within the working channel will also result in damage. The holmium laser may damage the working channel when the tip is very near the end of the working channel (Fig. 7-13).** To prevent this, the tip of the fiber must be seen in the central portion of the field of view. **The golden rule of safe holmium laser lithotripsy is “Do not step on the pedal if you cannot see the tip of the fiber in contact with the stone.”** This will prevent injury to the ureter, as well as damage to the ureteroscope.

A recent development in flexible ureteroscope design is the ability of the video system to prevent laser activation when the laser fiber is too close to the tip of the endoscope (Xavier et al, 2009). This “endoscope protection system” is activated in response to the video imaging system not “seeing” the blue color of the outer cladding of the laser fiber. When this “proximity alert” is activated, the laser will automatically pause firing to prevent damage to the scope.

Ureteroscopes, including the working channel, should be cleansed with warm water and a nonabrasive detergent after each use. Sterilization of ureteroscopes can be performed by gas (ethylene oxide), by soaking in a glutaraldehyde solution, or by use of the STERIS system (STERIS, Mentor, OH) (Gregory et al, 1988). The STERIS system provides automated washing and rinsing of the endoscopes in a peracetic acid solution.

Guidewires

Guidewires are essential to endourologic procedures. They are used for many portions of these procedures including establishment of percutaneous and ureteroscopic access, for straightening of the ureter, as a guide for dilation of the ureter or percutaneous tract, and for stent placement. There are many guidewires available differing in diameter, rigidity, tip design, materials, and coating. The choice of the most appropriate wire depends on the task involved and the patient’s anatomy and upper urinary tract problem being confronted.

The most common design is a solid stainless steel core around which an outer wire is wrapped. Nitinol (nickel-titanium) can be used for inner core construction, and this gives guidewires a kink-resistant, slightly stiffer character. Many newer wires (Zebra wire, Boston Scientific, Natick, MA; Roadrunner wire, Cook Medical, Bloomington, IN) have a nitinol core wire and polyurethane outer layer. These wires are well suited for passage of the ureteroscope because there is less friction of the ureteroscope over the polyurethane, and the stiffer core allows more reliable transmission of the “push” from the urologist to the tip of the ureteroscope. Angling of the tip is also possible because of the “memory” quality of the

nitinol material. When the outer polyurethane layer is coated with a hydrophilic polymer, these wires become exceptionally slippery. These “glide wires” are useful for negotiating around impacted ureteral calculi, tortuous ureters, and ureteral strictures. **Hydrophilic-coated wires are too slippery to be reliable safety wires, because of their tendency to slide out of the patient. When these wires are used for initial access, they are exchanged for a standard safety wire through an open-ended catheter.** A new hybrid designed wire (Sensor, Boston Scientific, Natick, MA) incorporating

a hydrophilic tip with a standard polytetrafluoroethylene (PTFE)-coated shaft may serve as both an access and safety wire for procedures in which access is difficult.

Guidewires for urology range in diameter from 0.018 to 0.038 inch, the most commonly used being 0.038 inch. Lengths vary from 80 to 260 cm. The most useful length for endourology is 145 cm. The tips of these wires are typically “floppy” for 1 to 3 cm. Benton and Newton wire designs have flexible tips of up to 15 cm and are seldom used today. Some wires have a movable core that can be

Figure 7-13. Image of the tip of a flexible ureteroscope that has been damaged by firing of the holmium laser within the working channel (arrow).

partially withdrawn to increase the length of the flexible tip. Other variable characteristics in guidewire construction include the distal tip design and the wire stiffness. The distal tip can be straight, angled, or J tipped. The rigidity of the wires can be varied by changing the diameter and design of the inner core wire. Stiffer wires can be useful for straightening out tortuous ureters or displacing a large prostatic lobe.

The choice of the most appropriate guidewire for the endourologic task at hand can mean the difference between success and failure. Despite all of these advances in wire design and construction, a 0.038-inch diameter, straight, flexible-tip, Teflon-coated, stainless steel wire is still a good choice for most cases.

Dilation Devices

Ureteral dilation is less necessary for ureteroscopy with the advent of newer, smaller-diameter ureteroscopes. Hudson and colleagues determined that the need for dilation was directly related to the diameter of the ureteroscope and was as low as 0.9% for 7.4-Fr diameter scopes (Hudson et al, 2005). When needed, ureteral dilation can be accomplished passively with indwelling stent placement or actively with dilating catheters or balloons. Ureteral dilating catheters are hydrophilic-coated polyurethane catheters tapered from a 6-Fr tip to a 12-Fr shaft and are passed over a wire to dilate the ureter (Gaylis et al, 2000). Ureteral balloon dilators are also passed over a wire, have a low profile of 3 to 8 Fr, and have dilation diameters of 12 to 30 Fr. **Dilation of the ureter beyond 15 Fr is rarely necessary for routine ureteroscopy.** Balloons can have maximum inflation pressures of 8 to 20 atmospheres depending on the design and the balloon material. Zero-tipped design ureteral balloon dilators are useful for dilating immediately adjacent to an impacted ureteral calculus. Ureteroscopic balloon dilators are 3 Fr in size, can be inflated to 12 Fr, and are passed directly through the ureteroscope. They are used to dilate under direct vision such as dilation of stenotic infundibula or calyceal diverticular necks. Once inflated, these ureteroscopic balloons cannot be removed through the ureteroscope but must be removed together with the ureteroscope.

Intraluminal Lithotripsy Devices

Intraluminal lithotripsy can be performed with several different modalities. Electrohydraulic lithotripsy (EHL) is widely available worldwide and is cost effective. Fragmentation of calculi is produced by shock waves generated from an electric spark produced on the tip of the electrode (Denstedt and Clayman, 1990). Fragmentation of most calculi is good but can be less effective for more dense calculus compositions such as cystine or calcium oxalate monohydrate. The small flexible EHL probes can be used with both rigid and flexible ureteroscopes. EHL can cause ureteral trauma because the energy is poorly focused. Although this rarely results in stricture formation, it can hinder visibility.

Pneumatic lithotripsy devices fragment calculi using mechanical ("jackhammer") energy (Schulze et al, 1993). Fragmentation is very good, and the potential for ureteral injury is low. Unfortunately, the mechanical energy can produce significant stone retropulsion. In general, the rigid probes are limited to use with rigid scopes. There are flexible probes available that can be used with flexible ureteroscopes, but they significantly limit scope deflection (Zhu et al, 2000).

The first laser successfully used for intraluminal lithotripsy was the pulsed dye laser. This laser energy is essentially no longer used because of the inability to fragment certain compositions of calculi, and the high cost of purchase and maintenance. The holmium:YAG laser has become the intraluminal lithotripsy energy of choice. It has a wavelength of 2100 nm, which is absorbed in 3 mm of water, making it very safe for use in urology (Blomley et al, 1995). Fragmentation is produced by a photothermal reaction with the crystalline matrix of calculi and produces stone dust rather than fragments, effectively removing a moderate volume of the stone (Zagone et al, 2002). The flexible quartz fibers can be used with both rigid and flexible ureteroscopes and are reusable. The holmium laser is effective for any composition of calculi (Bagley and Erhard, 1995; Denstedt et al, 1995; Erhard and Bagley, 1995; Grasso, 1996).

The thulium fiber laser (TFL) has been investigated as a potential alternative to the holmium laser for endoscopic lithotripsy. The TFL has a higher absorption coefficient and shorter optical penetration in water, which results in a 4-times lower ablation threshold for the TFL compared with the holmium laser. It is also a diode-pumped laser (holmium is flashlamp pumped), allowing greater control over the pulse length and duration (Hutchens et al, 2013). Most important, the TFL has been shown in vitro to have 5- to 10-times higher rates of stone vaporization than the holmium laser (Blackmon et al, 2010). There are still some practical fiber issues that need to improve before this laser can become commercially available, but it is a promising new development in endoscopic lithotripsy.

Stone Retrieval Devices

The components of stone retrieval devices include the control handle, the control wire, the sheath, and the device itself. Stone retrieval devices have shaft diameters that vary in size from 1.9 to 7.0 Fr. Devices for ureteroscopy are 3.0 Fr, and larger sizes can be used for cystoscopic or percutaneous procedures.

Three-pronged stone-grasping forceps are the safest instruments for removing calculi with the flexible ureteroscope. They permit disengagement of calculi that have been found to be too large to be safely removed from the ureter. In addition, the weak grasp will release the stone if too much force is applied, preventing damage to the ureter. This is critical when performing flexible ureteroscopy because there is no second channel to permit fragmentation of an unyielding stone trapped within a basket. Rigid ureteroscopes with two working channels have this additional degree of safety, permitting more routine use of baskets for removal of ureteral calculi. Although three-pronged graspers are the safest devices for ureteroscopic stone removal, they are seldom used because of improvements in the design and safety of stone baskets.

Stone baskets are available in helical, flat-wire, and other shapes. Baskets can also vary in the number and type of wires used. Two sheathing materials, PTFE and polyimide, are commonly used for

working instruments including stone baskets. A sheath made of polyimide is very durable but stiff and limits deflection of the flexible ureterscope. PTFE does not limit deflection as much as polyimide but is less durable and prone to stretching. Hybrid sheath designs incorporate Teflon at the tip and polyimide in the shaft, maximizing the advantages of each material. Helical baskets can be made with three-, four-, or double-wire designs with six or more wires. The double-wire designs have improved opening strength, which may facilitate removal of impacted calculi. Other basket designs such as the Parachute and LithoCatch from Boston Scientific (Natick, MA), the NCompass and NTrap from Cook Medical (Bloomington, IN), and the Sur-Catch basket from Olympus (Center Valley, PA) have more wires exposed on the distal end of the basket, making them effective for removing multiple small fragments. Helical baskets have round wires and, unlike flat-wire baskets, are safe to rotate within the ureter. They are opened above the stone and pulled down while rotating the basket to engage the stone.

Flat-wire baskets are nonhelical and are designed to have larger spaces among the four wires to allow engagement of larger stones. They were originally designed for percutaneous use, where, by filling the calyx when opened, they could more easily engage calyceal stones. They are also useful for biopsy of papillary ureteral tumors (Bagley, 1998).

There are two basket designs that attempt to combine the safety of three-prong graspers with the reliable grasp of baskets, the Graspit from Boston Scientific (Natick, MA) and NGage from Cook Medical (Bloomington, IN). These tipless devices open like three-pronged graspers and are advanced onto the stone, permitting easier disengagement of a calculus that is too large to be safely withdrawn from the ureter.

The latest material innovation is the use of nitinol for the basket wires. The soft nitinol wires have memory, maintain their shape, resist kinking, and therefore open more safely and allow disengagement of stones more reliably than stainless steel baskets. The unique qualities of nitinol also allow basket construction in a tipless fashion. These tipless baskets are soft and safe for use in the ureter and can be more fully deployed in a calyx without the interference from the tip, unlike stainless steel baskets.

Retropulsion Prevention Devices

Any type of intraluminal lithotripsy within the ureter will risk propelling the stone upward ("retropulsion"). The amount of retropulsion depends on the size and location of the stone, the degree of ureteral dilation, and the lithotripsy energy being used. If the stone is pushed back into the kidney, passing the flexible ureterscope into the kidney and treating the stone there is usually not a problem. However, prevention of retropulsion may be more time efficient and is particularly important when no flexible ureterscope is available.

Several devices are designed to prevent retropulsion of ureteral stones (Fig. 7-14). The Stone Cone and BackStop (Boston Scientific, Natick, MA), the NTrap (Cook Medical, Bloomington, IN), and the Accordion and CoAx (Accordion Medical, Indianapolis, IN) (Eisner et al, 2009; Wang et al, 2011; Wu et al, 2013). The Stone Cone is a 3-Fr device with a distal coil that can be deployed above the stone before fragmentation to help prevent stone migration. After fragmentation of the stone, it can be withdrawn to remove fragments. Any fragments too large to safely remove will be left behind because the coil simply unravels around the stone. The NTrap device is similar, 3 Fr, and is deployed above the ureteral stone. It is a meshlike wire basket that deploys perpendicular to the shaft, preventing migration of all but the smallest stone fragments. A recent development in the prevention of stone retropulsion is the BackStop device (Rane et al, 2010). This is a reverse-thermosensitive gel that is injected above the stone, conforming to and completely occluding the ureter. The deployment catheter can then be removed from the ureter, preventing hindrance of the ureteroscopic procedure. The gel is then dissolved by irrigating with cold saline solution.

Figure 7-14. Stone migration devices designed to prevent stone retropulsion during lithotripsy. *Left to right*, NTrap (Cook Medical, Bloomington, IN), Accordion (PercSys, Palo Alto, CA), and Stone Cone (Boston Scientific, Natick, MA).

Figure 7-15. The distal (*top*) and proximal (*bottom*) portions of a typical ureteral access sheath. The distal portion of the internal obturator (*blue*) is tapered. The access sheath is placed over a super-stiff guidewire, and the internal obturator is removed before ureterscope insertion. The proximal end of the obturator accepts a Luer-Lock syringe, facilitating retrograde pyelography.

Miscellaneous Devices

Other devices are available for ureterscope use. Small 3-Fr cup biopsy forceps can be used to perform biopsy of sessile tumors. A larger biopsy forceps, the BIGopsy (Cook Medical, Bloomington, IN) provides a much larger biopsy specimen, which may improve diagnostic yield (Wason et al, 2012). The large forceps requires backloading of the device into the ureterscope, and after the biopsy it must be removed together with the ureterscope. Electrodes are available in various shape including pencil point, ball point, and angled and straight tips. These can be used for fulguration and incision procedures such as endoureterotomy and endopyelotomy.

Ureteral Access Sheaths

Ureteral access sheaths allow repeated access to the intrarenal collecting system without having to replace the working guidewire with each passage of the endoscope (Fig. 7-15). They are available in 11- to 16-Fr sheath outer diameters. Currently available ureteral access sheaths are listed in Table 7-5.

In addition to facilitating stone fragment retrieval, access sheaths have been shown to decrease the intrapelvic pressure during ureteroscopy, which may decrease the risk of infectious complications from pyelovenous backflow (Auge et al, 2004). Their primary disadvantage is related to their size and their (small) potential for ureteral injury (Delvecchio et al, 2003; Traxer et al, 2013). Furthermore, the majority of intrarenal stones require only a single passage of the ureterscope to access and fully fragment the calculi. For these patients, an access sheath is usually unnecessary.

TABLE 7-5 Access Sheaths (Information Supplied by Manufacturers)

Fluoroscopy Equipment

Fluoroscopy is critical for ureteroscopic procedures and is needed for initial ureteral access, monitoring during endoscopy, and stent placement. Although tables designed for urologic endoscopy with fixed fluoroscopy units are available, mobile C-arm fluoroscopy units are preferable. **C-arm fluoroscopy units allow greater mobility, improved image quality, and less scatter radiation exposure to the surgeon because the x-ray source is below the patient.** Modern C-arm fluoroscopy units incorporate digital enhancement of the image and “last image hold” technology to minimize radiation exposure. Exposure can also be decreased by using image collimation and pulsed fluoroscopy. The urologist should control the fluoroscopy unit with foot pedal control, which will facilitate the speed of the procedure and minimize excessive fluoroscopy time. When possible, collimation and pulsed fluoroscopy should be employed to further limit exposure.

Ureteroscopy Technique

Preparation for Ureteroscopy

Upper tract imaging is performed to fully delineate the pathologic process being treated and to define the collecting system anatomy. This can be accomplished via intravenous pyelography or, more commonly, helical CT scan. Urinary tract infections are treated preoperatively, and infections above an obstruction are drained. **According to the AUA Best Practice Policy Statement, a routine preoperative antibiotic (first line, a fluoroquinolone) is given to all patients unless a culture provides antibiotic sensitivities for more targeted therapy (Wolf et al, 2008).** Anesthesia can be general (endotracheal or laryngeal mask), regional, or local with sedation (Vögeli et al, 1993; Hosking et al, 1996). It is important to communicate to the anesthesiologist the need for the patient to remain still throughout the procedure. Significant patient movement during rigid ureteroscopy can result in ureteral injury or perforation.

Endourologic procedures should be performed in a fully equipped operating room. The urologist should be prepared for any unanticipated problem encountered. In addition to routine Teflon-coated stainless steel guidewires, angled hydrophilic, nitinol core, and extra-stiff guidewires should be readily available. Dilation devices including dilating catheters, high-pressure balloon catheters, and zero-tipped balloon catheters are standard. Angled catheters that can be reliably rotated or “torqued” are very useful for gaining access around impacted calculi, strictures, or tortuous ureters. These include the Imager II catheter (Boston Scientific, Natick, MA) and the Kumpe catheter (Cook Medical, Bloomington, IN). The urologist should be very familiar with the endoscopes

available and the size of their working channels to choose appropriately sized working instruments when needed (see Tables 7-3 and 7-4). The largest working channels of most of the fiberoptic rigid ureteroscopes are just over 3 Fr, so instruments 3 Fr or smaller are appropriate. Backup flexible and semirigid ureteroscopes should also be available to ensure availability of appropriately functioning endoscopic equipment to treat pathology regardless of location in the upper urinary tract. A list of common items needed for successful ureteroscopy is provided in Box 7-3.

Accessing the Ureter

The patient is placed in the cystolithotomy position. If a longer rigid ureteroscope is being used, the contralateral leg is elevated to allow for easier introduction of the ureteroscope. With the advent of improved flexible ureteroscopes, most rigid ureteroscopy is confined to below the iliac vessels, and shorter rigid ureteroscopes can be routinely used, decreasing interference from the contralateral leg.

Cystoscopy is performed, primarily to place a safety guidewire but also to fully inspect the bladder. Usually a simple 0.038-inch diameter flexible-tip Teflon-coated guidewire is sufficient. A safety guide is critical during rigid ureteroscopy to maintain access and allow placement of a ureteral stent if any problems are encountered. Care must be taken when trying to gain access around an impacted stone because the ureter can easily be perforated. Manipulation of the guidewire around the stone may require use of an angled hydrophilic-coated wire, an angled torqueable catheter, or both. If a guidewire cannot be safely passed beyond the stone, direct inspection of the ureter up to the stone with the rigid ureteroscope will permit passage of the wire under direct vision. Once access above the stone has been achieved, the hydrophilic wire is exchanged for a more secure standard 0.038-inch diameter Teflon-coated guidewire. If there is any suspicion about possible infection above the stone, an open-ended catheter should be passed over the wire to aspirate the renal pelvis. The hydronephrosis can be decompressed to permit irrigation; if the fluid appears very cloudy, a stent is placed and the ureteroscopy is canceled until the infection has been treated. Before the ureteroscopy proceeds, the bladder is drained to permit accumulation of irrigation fluid during ureteroscopy and minimize buckling of the flexible ureteroscope into the bladder (Fig. 7-16).

Semirigid Ureteroscopy Technique

Because flexible ureteroscopes better accommodate the natural tortuosity of the ureter and with deflection provide better access to the intrarenal collecting system, semirigid ureteroscopy is usually limited to the ureter distal to the iliac vessels. The rigid ureteroscope is passed through the urethra and into the bladder

BOX 7-3 Common Supplies for Ureteroscopy**URETEROSCOPES****Rigid**

7-Fr or smaller semirigid ureteroscope

Figure 7-16. The bladder should be emptied before flexible ureteroscope passage to prevent buckling of the instrument within the bladder if resistance is met at the ureteral orifice.

Figure 7-17. Semirigid ureteroscope passage between two wires ("railroad" technique). After safety wire placement (*bottom wire*), a second wire (*top wire*) is passed through the working channel and up the ureter under fluoroscopic guidance and used to "tent open" the ureteral orifice. The ureteroscope is then gently advanced between the wires until ureteral access has been achieved.

under direct vision, usually with the aid of the video camera. Following the guidewire permits easy identification of the ureteral orifice.

By maneuvering the tip of the ureteroscope next to the guidewire posterolaterally, the physician can elevate the wire, thereby propping the ureteral orifice open to allow scope passage. If necessary, an additional guidewire can be passed through the ureteroscope just proximal to the intramural ureter. The ureteroscope is then rotated until it is directly between the two wires, which will hold the orifice wide open for entry of the scope (Fig. 7-17). Once the ureteroscope is through the intramural ureter, the additional guidewire can be

removed. This technique can also be useful for negotiating through tortuous segments of ureter and above the iliac vessels.

If the intramural ureter is too tight to allow safe passage of the ureteroscope, a dilating balloon catheter can be used to expand the orifice. In general, a 4-mm diameter balloon is sufficient. If there is a stricture beneath the stone that prevents safe visualization and lithotripsy, dilation beneath the stone is performed with a zero-tipped dilating balloon catheter. This balloon catheter can be passed over the safety wire immediately below the stone so dilation of the stenotic segment can be performed. The ureteroscope can then be safely introduced and the stone visualized. If the stone is impacted,

it can be helpful to gently manipulate it with the tip of the ureteroscope proximally out of the traumatized area of ureter for improved visibility and safer lithotripsy. If this is not possible, the holmium laser energy can be used in a “drill and core” technique. This will ablate the central portion of the stone, and the outer shell of the stone will protect the ureteral wall. The outer shell can then be safely fragmented. The stone can be fragmented until no fragments are greater than 2 mm, or alternatively it can be cleaved until the fragments are small enough to be easily removed with a helical basket. A stent is placed and in general is left for 3 to 7 days.

Flexible Ureteroscopy Technique

The cystoscope is removed and a dual-lumen catheter is passed over the initial guidewire. This dual lumen catheter is 10 Fr, which will gently dilate the ureteral orifice and allow placement of a second, working wire. The flexible ureteroscope is then passed in a monorail fashion over the taut working wire to the point of the pathology being treated. Dilation of the ureteral orifice with the dual-lumen catheter is usually sufficient to permit passage of the flexible ureteroscope. The working channel of flexible ureteroscopes is not centrally located, so the tip of the ureteroscope will be eccentrically positioned in relation to the guidewire. If the flexible ureteroscope does not pass the ureteral orifice, the scope should be rotated 90 to 180 degrees on the guidewire to better position the tip of the ureteroscope relative to the ureteral orifice. If difficulty passing the flexible ureteroscope through the ureteral orifice is still encountered, a dilating catheter (Nottingham) or a dilating balloon catheter can be used to dilate the ureteral orifice. **Formal ureteral dilation is reported in most ureteroscopy series to be needed in 8% to 25% of patients; this incidence has obviously decreased with the advent of smaller-diameter flexible ureteroscopes (Elashry et al, 1997; Grasso and Bagley, 1998; Tawfik and Bagley, 1999).**

If passing the flexible ureteroscope up the ureter is difficult in the absence of any significant ureteral stricture or other source of obstruction, the use of a nitinol core polyurethane-coated guidewire may be helpful. As previously discussed, these stiffer, smoother wires enable more efficient transmission of the push from the urologist to the tip of the ureteroscope.

The basic movements of the flexible ureteroscope include deflecting, rotating, and advancing and retreating the ureteroscope. The reticle of the flexible ureteroscope marks the plane of deflection, and rotation of the ureteroscope is often necessary to align this plane of deflection in the direction desired. **Failure to adequately rotate the ureteroscope is the most common mistake of the novice ureteroscopist.** Irrigation through the ureteroscope should be provided with a pressurized irrigation bag, roller pump, or hand-held syringe. **Normal saline should be used to prevent accumulation and absorption of hypotonic solution and resultant transurethral resection (TUR) syndrome.**

When the holmium laser is used, it is important to pass the laser fiber through a straightened flexible ureteroscope (confirmed fluoroscopically) to prevent damage to the working channel. Once the fiber has been passed beyond the tip, the ureteroscope can be deflected appropriately. The most commonly used sizes of holmium laser fibers include the 365-micron fiber and the 200-micron fiber. When significant deflection of the ureteroscope is needed, the 200-micron fiber is preferred because it does not limit the deflection of the ureteroscope as much as the larger fibers. The tip of the fiber must be in contact with the stone during treatment because the holmium laser energy is absorbed in 3 mm of water. **The holmium laser can damage the ureteroscope, the guidewire, and the ureteral wall. These problems can be avoided by not activating the laser unless the tip of the fiber is seen to be in contact with the stone (Beaghtler et al, 1998).** In addition, if the helium-neon aiming beam is not seen, the laser should not be activated because this may be an indication of fiber damage. Firing the holmium laser through a broken fiber can cause significant damage to the ureteroscope.

Once the pathology has been adequately addressed, a ureteral stent is typically placed and left indwelling for 3 to 5 days.

Postoperative pain management can be facilitated with the use of a cyclooxygenase-2 (COX-2) inhibitor and/or an α -adrenergic blocker (Nazim and Ather, 2012).

KEY POINTS: URETEROSCOPY

- Semirigid ureteroscopy is used below the iliac vessels and flexible ureteroscopy above.
- Semirigid ureteroscopes with two working channels permit better irrigation and offer the added safety of being able to pass a lithotripsy device through one channel when needing to fragment a stone engaged in a basket in the other channel.
- Flexible ureteroscopes must be straight during passage of a laser fiber or the working channel will be damaged.
- The golden rule of safe laser lithotripsy is “Do not step on the pedal if you cannot see the tip of the fiber in contact with the stone.”
- Stone baskets made of nitinol maintain their shape, resist kinking, and allow disengagement of stones more reliably than stainless steel baskets.
- Ureteral access sheaths facilitate repeated passage of flexible ureteroscopes and decrease the intrapelvic pressure during ureteroscopy.
- Mobile C-arm fluoroscopy is preferred because of greater mobility, improved image quality, and less scatter radiation exposure to the surgeon compared with urology tables with fixed fluoroscopy units.
- A routine preoperative antibiotic should be given to all patients undergoing ureteroscopy.
- Normal saline should be used for irrigation during ureteroscopy to prevent absorption of a hypotonic solution.

CONCLUSIONS

Over the past 150 years tremendous advances have been made in endoscope design, revolutionizing urologic surgery. Visualization of both the upper and lower urinary tracts is now routinely performed with rigid and flexible endoscopes. A variety of urologic conditions can be evaluated efficiently with minimal discomfort in the office by flexible cystoscopy. A wide array of benign and malignant conditions affecting the bladder and urethra can be managed transurethrally with rigid cystourethrosopes in the operating room with limited morbidity. Improvements in flexible ureteroscopes, working instruments, and endoscopic techniques have significantly improved our ability to effectively treat upper urinary tract problems as well. With continued innovation and refinement, the role of ureteroscopy in the treatment of complex intrarenal calculi, ureteral obstruction, and upper tract tumors should continue to expand.

Percutaneous Approaches to the Upper Urinary Tract Collecting System

J. Stuart Wolf, Jr., MD, FACS

History and Introduction

Indications for Percutaneous Access

Anatomic Considerations

Obtaining Percutaneous Access

Postprocedural Nephrostomy Drainage

Training in Percutaneous Access and Procedures

Complications

HISTORY AND INTRODUCTION

Commonly ascribed to [Goodwin and colleagues \(1955\)](#), the first therapeutic percutaneous nephrostomy was actually performed by Thomas Hillier in 1865 ([Bloom et al, 1989](#)). Hillier, at the Hospital for Sick Children at Great Ormond Street, repeatedly aspirated the hydronephrotic kidney of a young boy for symptom relief throughout a 4-year period until his death at 8 years of age. Subsequently there were a few reports of diagnostic percutaneous renal aspirations, but it was not until Goodwin and colleagues published their landmark report in 1955 that therapeutic percutaneous nephrostomy was rediscovered. Even then, the use of percutaneous access to the upper urinary tract collecting system was limited to drainage of obstructed kidneys until [Fernström and Johansson \(1976\)](#) described the percutaneous removal of renal calculi, termed “percutaneous pyelolithotomy.”

In the years since that report appeared, a number of procedures have been performed using the convenient and safe percutaneous route to access the upper urinary tract collecting system, including drainage of an obstructed kidney, nephrolithotomy, endopyelotomy, and resection of urothelial tumors. More recently, percutaneous access to portions of the kidney other than the collecting system has expanded the diagnostic and therapeutic choices for patients with renal diseases. Other chapters in this book address these indications, including Chapters 57 and 62. This chapter addresses only percutaneous access to the upper urinary tract collecting system, focusing on the creation, maintenance, and postprocedure management of the percutaneous tract. The final section of the chapter reviews the general complications of percutaneous access to the upper urinary tract collecting system. Specific aspects of the procedures performed through the percutaneous access are covered in Chapters 6, 49, 54, and 58.

INDICATIONS FOR PERCUTANEOUS ACCESS

Simple Drainage or Access

Percutaneous drainage of the upper urinary tract collecting system can be for diagnostic or therapeutic indications. **The only remaining popular indication for diagnostic percutaneous nephrostomy is to perform a Whitaker test**, which requires placement of a small-caliber nephrostomy tube through which contrast material is instilled at specific flow rates while pressures are measured to assess for ureteral obstruction (see a more detailed description in Chapter 49). In other cases, diagnostic nephrostography is performed as an adjunct to therapeutic percutaneous nephrostomy.

Therapeutic percutaneous nephrostomy tubes can be placed to drain the kidney (see Chapter 6) to access the upper urinary tract for direct instillation of therapeutic agents (see Chapter 58) or to perform a surgical procedure. **Percutaneous nephrostomy is indicated to drain the upper urinary tract collecting system in cases of obstruction at an intrarenal location, at the ureteropelvic junction, or anywhere in the ureter.** Obstruction of the lower urinary tract is best treated by drainage of the bladder rather than the kidney, unless secondary obstruction of the upper tract has developed that is refractory to vesicle drainage. An alternative to percutaneous drainage is drainage through a ureteral catheter or stent placed in a retrograde fashion (cephalad from the bladder to the kidney, as opposed to antegrade, which is placement from the kidney toward the bladder). **The choice of antegrade or retrograde drainage of the upper urinary tract collecting system depends on the indication for the procedure, patient’s medical condition, particular anatomy of the patient, and preferences of both the patient and the physician.**

All things being equal, a retrograde route to drainage is preferred instead of the antegrade route. This includes most cases of acute and chronic ureteral obstruction without infection ([Rosevear et al, 2007](#); [Wenzler et al, 2008](#)). **In the setting of upper urinary tract collecting system obstruction complicated by infection, however, drainage is an emergency and in many such cases percutaneous rather than retrograde drainage may be best** ([Ng et al, 2002](#)), unless retrograde drainage can be obtained expeditiously and assuredly. Percutaneous nephrostomy tubes and retrograde ureteral stents are generally equivalent in their capacity to resolve fever in patients with upper urinary tract obstruction and fever ([Pearle et al, 1998](#); [Goldsmith et al, 2013](#)), but in a given patient, circumstances may dictate a preference for one access instead of the other. Retrograde placement of a ureteral stent generally requires regional or general anesthesia, whereas a percutaneous nephrostomy tube can be inserted under local anesthesia; this is an important consideration for an ill patient. Because the percutaneous route includes a greater initial success rate than the retrograde route in cases in which the collecting system is dilated, it might be preferred in a patient who needs rapid intervention. This is especially true when the ureteral obstruction is long, severe, or involving the ureteral orifice—all of which can make retrograde stent placement more difficult. Conversely, untreated coagulopathy is a contraindication to percutaneous access, but internal ureteral stents can be placed safely in an anticoagulated patient. A final consideration is patient preference. Although the health-related quality of life for patients with percutaneous nephrostomy tubes and for those with internal ureteral stents is similar, a given patient may prefer one

route instead of the other (Joshi et al, 2001). For additional discussion of percutaneous nephrostomy versus internal ureteral stent for drainage of the upper urinary tract, see Chapter 6.

Percutaneous Surgery

Access into the upper urinary tract collecting system may be indicated to instill therapeutic agents directly. This includes chemolysis of urinary calculi and intracavitary topical therapy for urothelial carcinoma. In most cases, the access elected for the instillation will already be present after the preceding surgical procedure.

An important indication for percutaneous access into the upper urinary tract collecting system is the need for intrarenal or intraureteral surgery. This includes percutaneous endopyelotomy and endoureterotomy (see Chapter 49), nephrolithotomy, treatment of calyceal diverticula and hydrocalyces, and antegrade ureteroscopic treatment of large ureteral stones (see Chapter 54); it also includes percutaneous resection of urothelial tumors (see Chapter 58) and less-common procedures such as management of fungal bezoars. For all of these procedures, skillfully attaining access, properly managing postoperative drainage, and preventing and treating complications related to the percutaneous access are major procedural components. The remainder of this chapter centers on these topics.

ANATOMIC CONSIDERATIONS

Given that the visualization of the kidney and surrounding structures during standard percutaneous entry guided by fluoroscopy or ultrasonography is limited, understanding of the renal and perirenal anatomy is critical for obtaining access that is both effective and safe. Even armed with this knowledge, variations in anatomy can make access challenging for the experienced surgeon and prohibitive for the inexperienced one.

Perirenal Anatomy

The kidneys are well-protected organs, situated retroperitoneally and surrounded by adipose tissue. The short renal hilar vessels limit the mobility of the kidneys, although nephroptosis ("falling kidney") can occur, especially in thin women with a paucity of perirenal fat. In such cases the kidney not only descends but also rotates anteriorly. This can be troublesome during percutaneous punctures with the patient in a prone position.

The kidneys lie adjacent to the vertebral bodies, usually extending from the 11th or 12th thoracic to the 2nd or 3rd lumbar vertebrae (Fig. 8-1). The right kidney is displaced a few centimeters inferior to the left kidney. The longitudinal axis of the kidneys parallels the lateral edges of the psoas muscles, about 30 degrees from vertical, with the lower poles lateral to the upper poles. The kidneys are also tilted 30 degrees off the frontal plane, with the lower poles

anterior to the upper poles. Finally, the kidneys are rotated out of the frontal plane as well, with the lateral aspect of the kidney posterior to the medial aspect, such that each kidney is rotated 30 degrees posteriorly from the renal hilum.

Immediately posterior to the kidneys are the quadratus lumborum and psoas muscles, except at the upper poles where the diaphragm is posterior (Fig. 8-2). The pleura can be violated during percutaneous entry into the upper pole of the kidney. This risk is greater as the access to the kidney is moved cephalad. The lung itself lies above the 11th rib, so direct lung injury is unlikely unless the 10th intercostal space (superior to the 11th rib) is used as the entry site. The ribs curve inferiorly from medial to lateral, such that more portions of the kidney can be approached subcostally with a medial as opposed to a lateral access site.

The lateral, anterior, and medial perirenal relationships are more varied than the posterior ones (Fig. 8-3). On the right side, the liver is anterior to the upper pole of the kidney and can extend in some individuals to cover the entire anterior surface. On the left, the spleen covers less of the kidney anteriorly. Both the liver and spleen can extend lateral to the kidneys and are therefore at risk of injury with a lateral puncture into the kidney. The ascending and descending colon can be lateral or even posterior to the right and left kidneys, respectively. The apposition of the colon to the kidney varies with location; it is greatest on the left side and at the lower pole. In one study of computed tomograms, the left colon was posterior in 16.1% of cases, and the right colon was posterior in 9% of cases at the level of the lower pole. At the midaspect of the kidney the colon was posterior in 5.2% and 2.8%, respectively, and at the upper pole 1.1% and 0.4%, respectively (Boon et al, 2001).

Figure 8-2. Muscles and ribs posterior to the kidneys.

Figure 8-1. Location of kidneys in the retroperitoneum.

Figure 8-3. Viscera lateral, anterior, and medial to the kidneys.

Additional visceral relations to the kidney include the adrenal glands (medial to the upper pole of both kidneys), the duodenum and gallbladder (anterior and medial to the right kidney), and the tail of the pancreas (anterior and medial to the left kidney). These structures can be injured with a misdirected or excessively deep puncture.

Renal Parenchyma and Collecting System

The renal parenchyma is composed of cortical and medullary tissue. The renal cortex is the outermost layer. It contains the glomeruli and proximal and distal convoluted tubules. The more interior medulla contains the renal pyramids. These are inverted cones (the base of which is superficial and the apex of which is deep) that comprise the loops of Henle and the collecting ducts, which coalesce at the apex of the pyramid into papillary ducts that open on the surface of the renal papillae. There are approximately 20 papillary ducts draining into each papilla. The columns of Bertin are invaginations of cortical tissue that surround the renal pyramids except at their apices.

The renal papillae drain into the minor calyces, which are the most peripheral portions of the intrarenal collecting system. If only one papilla drains into a minor calyx, it is described as a simple calyx. When there are two or more papillae entering the calyx, it is termed a *compound calyx*. The outermost wall of the calyx, into which the papilla is set, is the calyceal fornix. There are 5 to 14 minor calyces in each kidney (mean of 8, with 70% of kidneys having 7 to 9 minor calyces) (Sampaio and Mandarim-de-Lacerda, 1988). There are three calyceal groups: the upper, middle, and lower. Compound calyces are the rule in the upper calyceal group, are common in the lower calyceal group, and are rare in the middle calyceal group. The minor calyces, either directly or after coalescing into major calyces, drain by infundibula into the renal pelvis (Fig. 8-4). Occasionally a minor calyx will open directly

into the renal pelvis without an intervening infundibulum. Some infundibula are unusually narrow, even if they drain adequately, and they can present an obstacle to endoscopy, especially with the relatively large rigid nephroscope.

The compound calyces of the poles of the kidney are oriented facing their respective poles. The simple calyces usually come in pairs, with one facing anteriorly and one facing posteriorly (Fig. 8-5). The upper pole calyceal system almost always contains at least one compound calyx, and in some cases this is the only calyx in the system. Drainage of the upper pole into the renal pelvis is by a single midline infundibulum in the majority of kidneys. The lower pole system often contains a compound calyx as well. The calyceal drainage from the lower pole is via a single infundibulum in about half of human kidneys and through a series of paired anterior and posterior calyces in approximately half of kidneys. With compound calyces rare in the middle calyceal system, the middle calyces are typically arranged in a series of paired anterior and posterior calyces. In about two thirds of kidneys, there are two major calyceal systems—an upper one and lower one—and the middle calyces drain into either or both systems. In the other third of kidneys, the middle calyceal system is distinct from the upper and lower systems, either coalescing into a middle major calyx before emptying into the renal pelvis or with drainage of the middle minor calyces directly into the renal pelvis through short infundibula.

An important consideration for percutaneous renal surgery is the determination of the anteroposterior orientation of the calyces, because access (from the typical posterior or posterolateral approach) into a posterior calyx allows relatively straight entry into the rest of the kidney, whereas percutaneous puncture of an anterior calyx requires an acute angulation to enter the renal pelvis, which may not be possible with rigid instrumentation (Fig. 8-6). Efforts have been made to determine which calyces are likely to be anterior and which are likely to be posterior, solely on the basis of their mediolateral position on anteroposterior radiography. The distinction pertains to the middle and lower calyceal system, which contains (in almost all middle systems and approximately half of the lower system) paired anterior and posterior minor calyces. The upper pole system, with its almost uniformly compound calyceal system, is less problematic in this regard. Paired anterior and posterior calyces usually enter at about 90 degrees from each other. As such, the relative mediolateral orientation (on anteroposterior radiography) is determined by the relationship of this 90-degree unit to the frontal plane of the kidney. In a Brödel-type kidney, this unit is rotated anteriorly, such that the posterior calyces are about 20 degrees behind the frontal plane and the anterior calyces are 70 degrees in front of the frontal plane. The posterior calyces are lateral, and the anterior calyces are medial in this case. The Hodson-type kidney is the opposite; the calyceal pairs are

Figure 8-4. Upper urinary tract collecting system.

Figure 8-5. Calyceal orientation of polar and middle calyces. (From Smith AD. Controversies in endourology. Philadelphia: Saunders; 1995.)

Figure 8-6. Relation of anterior and posterior calyces to renal parenchyma in Brödel-type kidney (A) and Hodson-type kidney (B). The optimal site of percutaneous entry from the posterior aspect of the kidney is into a posterior calyx because the path into the renal pelvis is fairly straight. If entry is into an anterior calyx (from the posterior aspect of the kidney) then an acute angulation must be made to enter the renal pelvis, which may not be possible with rigid instrumentation. (From Smith AD. *Controversies in endourology*. Philadelphia: Saunders; 1995.)

rotated posteriorly, with the posterior calyces 70 degrees behind the frontal plane and appearing medial and with the anterior calyces 20 degrees in front of the frontal plane and appearing lateral (see Fig. 8-6). Most right kidneys have a Brödel-type orientation (posterior calyces are lateral), and most left kidneys have a Hodson-type orientation (posterior calyces are medial). The results of one study showed that in the lower calyceal system, the medial calyces are anterior and the lateral ones are posterior most of the time (Eisner et al, 2009). Because variation is considerable, the mediolateral orientation of the calyces on anteroposterior radiography cannot be used to determine reliably the optimal calyx for entry, and additional maneuvers are required to determine the exact calyceal anatomy. One reliable anatomic distinction is that the upper calyceal group is situated in a mediolateral orientation in 95% of kidneys, in contrast to the anteroposterior orientation of the middle and lower calyceal groups in 100% and 95%, respectively (Miller et al, 2013.) This means that most calyces of the upper pole are suitable for percutaneous access from the posterior approach, whereas care must be taken to select a posterior minor calyx in the middle and lower groups. Within the lower calyceal group, the most inferior calyx is usually anterior, but the next most cephalad calyx is usually posterior (Miller et al, 2013).

Intrarenal Vasculature

Although the renal arterial anatomy is variable, in general the main renal artery divides into an anterior and a posterior branch. The former then divides within or before the renal sinus into four anterior segmental arteries: the apical and lower segmental arteries (which supply the tip of the upper pole and the entire lower pole, respectively), and the upper and middle segmental arteries (which supply the remainder of the anterior half of the kidney). The posterior branch of the renal artery supplies the remainder of the posterior half of the kidney (Fig. 8-7). After the anterior segmental arteries and the posterior branch of the renal artery enter the renal parenchyma, they divide into interlobar arteries, which are also called infundibular arteries owing to their course adjacent to the calyceal infundibula of the renal collecting system. At the cortico-medullary junction, near the base of the renal pyramids, each interlobar artery usually divides into two arcuate arteries that run along the renal pyramid. The next division is into the interlobular arteries, which run along the outer surface of the renal pyramids and are derived at right angles from the arcuate arteries. The final divisions, the afferent arterioles of the glomeruli, come off the interlobular arteries in the peripheral renal cortex. Each renal

Figure 8-7. Arterial supply to the kidney. The kidney is supplied by the anterior and posterior branches of the main renal artery. The anterior branch supplies both the anterior half of the kidney and the polar regions via four segmental branches. The posterior branch of the renal artery supplies the posterior aspect of the kidney (represented by the shaded region). An avascular plane, known as Brödel line, separates the anterior and posterior circulations.

arteriole is an “end-artery,” meaning that each cell in the kidney derives its blood supply from one arteriole. For this reason renal arterial vascular injury must be avoided to prevent loss of renal function. The potential for arterial injury is least in the Brödel line, which is an avascular plane approximately at the lateral margin of the kidney, extending from the superior apex of the kidney (limited by the circulation of the apical anterior segmental artery) to the lower pole of the kidney (limited by the circulation of the lower anterior segmental artery). **Additionally, the safest place to access percutaneously the collecting system is directly into the calyceal fornix, because this will avoid the interlobar (infundibular) arteries adjacent to the calyceal infundibula and the arcuate arteries that skirt the renal pyramid (Sampaio et al, 1992).**

The venous anatomy of the kidney does not have the same defined structure as the arteries. Moreover, there is free cross-circulation among the intrarenal veins via arcades. This enhances vascular outflow from the kidneys, reduces the risk of venous congestion, and makes renal venous injury less damaging to renal function than arterial injury.

KEY POINTS: ANATOMIC CONSIDERATIONS

- Both the diaphragm and pleura can be violated during percutaneous entry into the upper pole of the kidney.
- The ascending and descending colon can be lateral or even posterior to the right and left kidneys, respectively. The apposition of the colon to the kidney varies with location; it is greatest on the left side and at the lower pole.
- An important consideration for percutaneous renal surgery is the determination of the anteroposterior orientation of the calyces.
- The mediolateral orientation of the calyces on anteroposterior radiography cannot be reliably used to determine the optimal calyx for entry.
- Most calyces of the upper pole are suitable for percutaneous access from the posterior approach, whereas care must be taken to select a posterior minor calyx in the middle and lower groups
- The safest place to access percutaneously the collecting system is directly into the calyceal fornix.

OBTAINING PERCUTANEOUS ACCESS

Adequate percutaneous access to the upper urinary tract collecting system is a critical part of the percutaneous procedure. As time passes, more urologists are being trained to attain percutaneous access (Spann et al, 2011), but only a minority of urologists in the United States maintains this skill in practice (Bird et al, 2003; Lee et al, 2004a). Survey data from the United Kingdom suggest that the attainment of access for percutaneous surgery is almost equal between urologists and radiologists, with a combined urologist-radiologist team used in the most complex cases (Aslam et al, 2011). Although there is some controversy regarding the success and complications associated with access for percutaneous renal surgery attained by urologists versus radiologists (Watterson et al, 2006; El-Assmy et al, 2007; Tomaszewski et al, 2010a), the critical distinction in ensuring effective access for a subsequent percutaneous procedure is not who obtains access but rather that the access for urologic surgery is directed by a urologist. **The optimal situation is for the urologist to be present at the time access is attained, either performing the access procedure or actively directing the radiologist.** When access is gained without input of the urologist (whether present in person or directed beforehand), the access site is not acceptable for the subsequent percutaneous procedure in a large portion of cases (Tomaszewski et al, 2010a).

Periprocedural Antimicrobials

Prevention of infectious complications is a major consideration when considering percutaneous access into the upper urinary tract collecting system. **In an elective setting, confirmation that urine is sterile is optimal.** In cases of anatomic abnormality, recent hospitalization, distant coexistent infection, recent catheterization, or other situations that suggest increased likelihood of bacteriuria, a urine culture is recommended. **In the setting of an externalized catheter or staghorn renal calculus, bacteriuria is likely and a preoperative urine culture should be considered standard practice.** In other cases, a screening urinalysis may be adequate, with subsequent culture if the urinalysis is suspicious for infection. When there is bacteriuria, a therapeutic course of culture-directed antimicrobials should be administered to sterilize the urine. Optimally, a repeat urine culture should be obtained to confirm urine sterility, although this might not be practical. In cases with colonized exogenous material such as an externalized urinary

catheter or an infected calculus, it may not be possible to eradicate the infection before the percutaneous procedure. The goal then is to suppress the bacterial count before intervention.

The American Urological Association (AUA) recommends periprocedural antimicrobial prophylaxis for all cases of percutaneous renal surgery (Wolf et al, 2008). Although there are no randomized, controlled trials to support this recommendation, nonrandomized data suggest a postprocedure urinary infection rate of 35% to 40% if antimicrobial prophylaxis is not used compared with 0% to 17% if prophylaxis is used (Charton et al, 1986; Darenkov et al, 1994). In a large retrospective but matched case-control study, comparing 162 patients with and 162 patients without antimicrobial prophylaxis undergoing percutaneous nephrolithotomy, the rate of fever and other postoperative complications was threefold to tenfold greater in the group without antimicrobial prophylaxis (Gravas et al, 2012). The need for antimicrobial coverage for simple percutaneous drainage of the upper urinary tract collecting system is not certain.

Antimicrobial coverage should include organisms common to the urinary tract (*Escherichia coli*, *Proteus* sp., *Klebsiella* sp., *Enterococcus* sp.) and the skin (*Staphylococcus aureus*, coagulase-negative *Staphylococcus* sp., group A *Streptococcus* sp.). Recommended agents include first- and second-generation cephalosporins; aminoglycosides (or aztreonam in patients with renal insufficiency) plus either metronidazole or clindamycin; ampicillin/sulbactam; or a fluoroquinolone. Although there are some series that suggest that the administration of antimicrobials for the week before percutaneous nephrolithotomy reduces the risk of infectious complications (Mariappan et al, 2006; Bag et al, 2011), the preponderance of evidence suggests that when the antimicrobial is being administered only for prophylaxis (i.e., not treatment of known or presumed infection), immediate perioperative treatment for percutaneous nephrolithotomy (≤ 24 hours) is just as effective as a longer course and is therefore preferred (Dogan et al, 2002; Demirtas et al, 2012; Seyrek et al, 2012; Tuzel et al, 2013). A short (≤ 24 hours) course of antimicrobials at the time of nephrostomy tube removal also can be considered (Wolf et al, 2008).

Management of Anticoagulation

With the increasing use of antiplatelet and anticoagulant medications in the general population, the urologist is faced more frequently with planning percutaneous renal surgery for patients taking such medications (Riley and Averch, 2012). In addition, other medications—such as nonsteroidal anti-inflammatory agents and some nutritional supplements—include anticoagulant or antiplatelet activity. Except as outlined in the following, these medications should generally be discontinued before percutaneous renal surgery. The preoperative cessation periods vary: herbal medicines, 1 week; aspirin, 1 week; warfarin, 5 days; clopidogrel, 5 days; nonsteroidal anti-inflammatory agents, 3 to 7 days. In their consensus document, the International Consultation on Urological Diseases and AUA (Culkin et al, 2014) recommend the following as related to percutaneous renal surgery:

1. Oral anticoagulant or antiplatelet activity medications should be discontinued before percutaneous renal surgery (except as noted in the following). Bridging with heparin derivatives may be required with resumption of oral anticoagulant or antiplatelet agents as soon as the risk of periprocedural hemorrhage has lessened. Expert multidisciplinary management may be required for those at high thromboembolic risk.
2. Because withdrawal of dual antiplatelet therapy (i.e., aspirin plus clopidogrel) should never occur within 12 months of drug-eluting stent placement or within 3 months of bare metal stent placement, elective percutaneous renal surgery should not be performed within these time periods.
3. For patients on clopidogrel or aspirin for secondary stroke prevention, especially after a recent stroke, cessation of the agent may be ill advised, and neurologic consultation is recommended if percutaneous renal surgery is being considered.

4. Low-dose aspirin can be continued in the perioperative period, although in patients without specific medical indications the surgical team may elect to hold the agent perioperatively.
5. For patients taking warfarin who are at high risk of thrombosis (any mechanical mitral valve replacement or a mechanical aortic valve with any risk factor), warfarin should be stopped 5 days before the surgical procedure and appropriate bridging therapy (heparin or heparin-derivative) should be instituted. For patients taking warfarin for other indications (atrial fibrillation, history of deep venous thrombosis, etc.), bridging may not be required.

In some patients who must continue anticoagulant or antiplatelet therapy, ureteroscopy might be a satisfactory alternative to percutaneous renal surgery because it can be performed with ongoing anticoagulant or antiplatelet therapy.

Local and Regional Anesthesia

Regardless of the type of primary anesthesia that is used for percutaneous renal surgery, the addition of local and regional anesthesia may be beneficial. Of eight randomized controlled trials assessing the impact of tract infiltration with various local anesthetics versus placebo on early postoperative pain and narcotic use, all but one demonstrated a benefit (Haleblian et al, 2007; Ugras et al, 2007; Jonnavithula et al, 2009; Gokten et al, 2011; Akbay et al, 2012; Shah et al, 2012; Kirac et al, 2013; Parikh et al, 2013). Additionally, intercostal nerve blocks and thoracic paravertebral block with long-acting local anesthetics have provided a similar benefit in randomized controlled trials (Ak et al, 2013; Honey et al, 2013; Ozkan et al, 2013).

Patient Positioning

Goodwin and colleagues (1955) described the prone position for percutaneous access to the upper urinary tract collecting system, and with time this position became standard. A “prone-flexed” position has also been described (Ray et al, 2009). The prone position has the advantage of presenting a large surface area (the patient’s back) that provides many choices of access sites and a stable horizontal working surface. The posterior or posterolateral approach is the most direct one to the desirable posterior calyces and comes closest to approaching the kidney through the Brödel avascular line. Prone positioning does have some disadvantages, however. It is associated with a decrease in cardiac index (Hatada et al, 1991), and in cases where inadequate padding is provided it is associated with decreased pulmonary capacity, although if enough padded support ensures free abdominal and chest wall movement, then pulmonary capacity is greater in the prone compared with the supine position (Edgcombe et al, 2008). The anesthesiologist has poor access to the airway with the patient in the prone position. Prone positioning might not be possible in patients with morbid obesity and/or spinal concavity, and the prone position can be associated with neuromusculoskeletal complications such as nerve compression or stretch injury, ocular or facial injury, and rhabdomyolysis. Finally, the prone position requires that the surgeon stand, often holding instruments at a distance using outstretched arms, which leads to surgeon fatigue. To address these deficiencies, urologists have introduced supine and lateral decubitus positioning for percutaneous renal surgery.

Valdivia Uribe and colleagues (1987) first reported the supine approach to percutaneous nephrolithotomy, culminating in their 1998 review of 557 patients with percutaneous nephrolithotomy performed in this position (Valdivia Uribe et al, 1998). They reported few complications; there were no hydrothoraces or pneumothoraces, no colon injuries, and only a 0.5% rate of major hemorrhage (see later for further discussion of complications). Variations of this position include completely supine, supine with the ipsilateral flank elevated, and supine combined with varying degrees of ipsilateral flank elevation (in some with 90-degree rotation) and asymmetric lithotomy position (Falahatkar et al, 2008; Papatsoris et al, 2008; Scoffone et al, 2008; Zhou et al, 2008; Moraitis et al, 2012). In the

prone position, with a posterior or posterolateral skin entry, the posterior calyces are the best to enter because they allow access to the renal pelvis and the rest of the kidney. In the supine position, the skin entry site is lateral or anterolateral, so the best calyces to enter are often the anterior ones. For a procedure such as percutaneous nephrolithotomy with the patient in the supine position, the access sheath is angled toward horizontal (compared with vertical during percutaneous nephrolithotomy in the prone position), which reduces the pressure in the collecting system and facilitates stone fragments to wash out through the sheath. Supine positioning does not require repositioning after induction of anesthesia, and the urethra is more easily accessed than in the prone position. The supine position is a safer position with regard to neuromusculoskeletal complications, and the anesthesia team may prefer this position (Atkinson et al, 2011). Finally, because the percutaneous entry is more lateral than during a prone procedure, the instruments are closer to the surgeon, which results in less physical strain on the surgeon and the opportunity for the surgeon to sit during the procedure.

There are some disadvantages to the supine position for percutaneous renal surgery, however. First, it is not familiar to most urologists because the prone position is used in most training programs. Second, the reduced pressure in the collecting system results in a lower volume and thus less room for visualization and manipulation. Third, upper pole calyceal access is more difficult in the supine compared with prone position, and percutaneous tract length is longer than in the prone position (Azhar et al, 2011; Duty et al, 2012). Finally, with optimal placement of pads and bolsters, the prone position may provide better ventilation than the supine position (Edgcombe et al, 2008, Atkinson et al, 2011).

In a large, multi-institutional and retrospective study of percutaneous nephrolithotomy, including 4637 patients and 1138 patients with prone and supine positioning, respectively, operative time and stone-free rates favored the prone position, but some patient safety parameters favored the supine position (Valdivia et al, 2011). Two meta-analyses of supine versus prone positioning for percutaneous nephrolithotomy, 1 incorporating two randomized controlled trials and 2 case-control studies (Liu et al, 2010) and 1 including the same 4 studies plus 27 case series (Wu et al, 2011), both documented conclusions that operative time is shorter in the supine position but that there are no differences in other parameters.

The flank (lateral decubitus) position, which first was described by Kerbl and colleagues (1994), is less commonly used for percutaneous renal surgery. This position allows simultaneous access to the anterior and posterior aspects of the kidney and appears to be particularly useful for morbidly obese patients or those with spinal deformities in whom both supine and prone positioning are difficult (Gofrit et al, 2002; Basiri et al, 2008b; El-Husseiny et al, 2009). Randomized trials comparing flank to prone position (Karami et al, 2010) and flank to supine to prone positions (Karami et al, 2013) showed no difference in outcomes.

Although both the supine and flank positions offer some potential benefits over prone positioning in certain settings, particularly morbid obesity and spinal deformities, the evidence suggests no overwhelming differences, so surgeon preference can determine the choice of position for percutaneous renal surgery. As such, the remainder of this chapter concerns access into a posterior calyx from a posterior or posterolateral direction with the patient in the prone position, which remains the standard.

The initial step in a percutaneous procedure is often cystoscopic retrograde placement of a ureteral catheter. This can be performed with the patient in prone position (using a flexible cystoscope) or in lithotomy with subsequent prone repositioning. In the “upside-down” bladder, the bubble of air from initial introduction of the cystoscope often approximates the location of the ureteral orifices. Prone cystoscopy can be performed on a standard operating or fluoroscopy table but is simplified by the use of “spreader bars” on the foot of the table (also called a “split-leg table”). Abducting the legs with the knees straight spreads the legs. This provides better access to the external urethral meatus.

Figure 8-8. Padding for prone positioning.

Careful placement of padding is important in the prone position (Fig. 8-8). Support of the head with padding in a neutral position allows access to the mouth. Make sure there is not undue pressure on the facial bones, nose, and ears. Place the ipsilateral arm above the head to move it from the operative field, with the shoulder and elbow at right angles, and pad generously. Position the contralateral arm in the same way, or leave it straight and tucked at the side. Rest the lateral aspects of the chest on rolled blankets or other bulky foam or gel bolsters to allow for chest and abdominal wall expansion. Alternatively, purpose-made pads and supports provide more assured patient positioning (Papatsoris et al, 2009). Provide support under the ankles to take pressure off the feet, and pad the knees and feet. Prepare the perineum and ipsilateral flank sterilely, and cover unsterile areas with drapes. Cover the flank with an adherent drape that incorporates a fluid collection pouch.

Choice of Access Site to the Collecting System

The access site into the upper urinary tract collecting system is a critical determinant of the success of the subsequent procedure. In the prone position, the preferred calyces are the posterior ones (or the posterior aspect of compound calyces), which allow better access to the remainder of the collecting system. The anterior calyces can usually be approached through a posterior calyx. In cases that involve a calyceal diverticulum, narrow infundibulum, or pathology in an eccentric anterior calyx, direct puncture into an anterior location might be required. The ability to access the rest of

the collecting system is limited with such access. **Percutaneous access should never be directly into an infundibulum or the renal pelvis, which greatly increases the risk of vascular injury (Sampaio et al, 1992).** The state of the renal parenchyma overlying the intended calyx of entry also must be considered because if it is thin, the tract into the collecting system may not close well after nephrostomy tube removal.

An upper pole calyx is generally the most versatile site through which to enter the upper urinary tract collecting system. The renal pelvis, lower pole calyces, and ureter usually can be entered with a rigid nephroscope from a well-placed upper pole access. Because of the posterior tilt of the upper pole of the kidney, the lower pole does not offer assured access to the upper pole. Access to the middle calyces will usually require a separate access or use of flexible instrumentation. Often a middle calyx will offer adequate access to the ureteropelvic junction, as needed in cases such as endopyelotomy. In other cases, the calyx of entry should be selected based on the distribution of the pathology to be treated. Efforts should be made to select a calyx that will allow treatment through a single site with rigid instrumentation. If this is impossible, then one should select the site that will allow the largest portion of the pathology to be treated. The remaining pathology can be addressed with a second (and rarely a third or more) access or with flexible instrumentation through the initial access site.

Subcostal access is the safest route to the kidney because pleural injuries are rare with entry below the 12th rib. Nonetheless, if entry directly above the 12th rib (11th intercostal space) provides the best access to the optimal calyx, then the benefit generally exceeds the risk (Fig. 8-9). Entry above the 11th rib, however, has a greater potential for pleural and even lung injury, so when the best access calls for a direct puncture above the 11th rib, additional maneuvers should be considered to displace the kidney inferiorly. These include: cephalad tilt of a subcostal access sheath or access needle placed into a lower calyx (Karlin and Smith, 1989; Lezrek et al, 2011); gentle traction on a through-and-through guidewire placed through a lower pole access (Goyal et al, 2012); and attaining access during full inspiration (Falahatkar et al, 2010). Another alternative is to angle the access tract cephalad from a subcostal entry site (Liatsikos et al, 2005; Rehman et al, 2008). This approach provides limited access to the rest of the kidney. All of these alternatives can result in damage if the kidney is moved caudally with excessive force. A multicenter retrospective study of patients undergoing percutaneous nephrolithotomy via upper pole access showed that patients with an intercostal approach experienced greater stone-free rates, fewer complications, and reduced

operating times compared to patients with a subcostal approach (Lang et al, 2009). Access above the 10th rib is associated with a high incidence of pleural violation and lung injury and should be avoided unless absolutely necessary. Thoroscopically guided access superior to the 10th rib can be performed to reduce the risk of lung injury (Finelli and Honey, 2001).

Although standard preoperative ultrasonography or intravenous urography is sufficient in many cases for treatment planning, in complex cases cross-sectional imaging with computed tomography (CT) or magnetic resonance imaging (MRI) might be helpful. CT is a standard at many centers. For a more accurate representation of the renal collecting system, three-dimensional imaging reconstructions using CT or MRI are useful (Hubert et al, 1997; Buchholz, 2000; Ng et al, 2005; Thiruchelvam et al, 2005; Ghani et al, 2009; Kalogeropoulos et al, 2009; Patel et al, 2009). With specific timing of contrast injections and CT imaging, the vascular and collecting systems can be visualized simultaneously (Dalela et al, 2009).

Retrograde Assistance for Access into the Collecting System

One of the advantages of urologist participation in obtaining the initial percutaneous access is the opportunity to provide retrograde transurethral assistance. This assistance can take many forms, from placing a ureteral catheter, to inserting a flexible ureteroscope, to obtaining the percutaneous access using a retrograde-inserted device.

The simplest form of retrograde transurethral assistance is to place a 5- or 6-Fr straight ureteral catheter up into the renal pelvis (Fig. 8-10 on the Expert Consult website). Air and/or contrast material can be injected to delineate and dilate the intrarenal collecting system anatomy (Fig. 8-11 on the Expert Consult website), and a guidewire can be passed from below and grasped by the nephroscope to establish through-and-through access from the external urethral meatus to the percutaneous entry site. A dual-lumen catheter can be placed as well. The small caliber of either catheter, however, does not provide much outflow from the kidney and may not prevent stone or tumor fragments from passing into the ureter along the catheter. A ureteral occlusion balloon catheter, which incorporates an approximately 15-Fr spherical balloon on the distal tip, more consistently prevents material from migrating down the ureter. The balloon should be carefully inflated in the renal pelvis, making sure the balloon is not in the ureter—which could lead to ureteral rupture—and then gently pulled down to occlude the ureteropelvic junction (Fig. 8-12). Another alternative is to place a ureteral access sheath (usually 11 to 15 Fr) over a retrograde-inserted guidewire (Landman et al, 2003). The large outer diameter of the sheath effectively prevents particles from passing around the sheath into the ureter, and the large inner diameter affords excellent outflow of small stone particles. The disadvantages of using a ureteral access sheath include the potential ureteral trauma from passing such a large device into the ureter and the clogging of the catheter lumen by oversized stone fragments.

A ureteroscope passed retrograde can greatly facilitate percutaneous entry into the intrarenal collecting system (Grasso et al, 1995; Kidd and Conlin, 2003; Patel et al, 2008) by allowing the surgeon to observe and correct the percutaneous placement of a needle. A basket can then be passed through the ureteroscope to grasp the end of the percutaneous guidewire; pulling this out through the urethra provides through-and-through access (Fig. 8-13). Even if the pathology being addressed is so large that direct visualization of the percutaneous needle is obscured (e.g., complete staghorn calculus), one can still use the ureteroscope to rapidly attain through-and-through access. Moreover, the ureteroscope may have better access to some sites in the kidney than the nephroscope and can be used to assist in the procedure (e.g., fragment or relocate stones, fulgurate small tumors). Retrospective nonrandomized comparisons of ureteroscopic-assistance versus solely fluoroscopic guidance for access during percutaneous nephrolithotomy suggest

Figure 8-9. Subcostal and supracostal percutaneous access to an upper pole calyx. The supracostal approach provides more direct access and provides a better angle for endoscopy of the rest of the kidney.

Figure 8-10. Straight ureteral catheter has been passed up into stone-containing renal pelvis.

Figure 8-11. Retrograde pyelogram with air and contrast shows air in upper pole compound calyx and posterior lower pole calyx.

Figure 8-12. Occlusion balloon inflated and snugged down at ureteropelvic junction of contrast-filled upper tract collecting system.

that the former may be associated with a lower transfusion rate (Sountoulides et al, 2009), decreased fluoroscopy time, reduced need for multiple accesses, and a reduction in the early termination of the procedure as a result of hemorrhage (Isac et al, 2013).

The “ultimate” retrograde assistance to percutaneous access into the upper urinary tract collecting system is the retrograde approach to percutaneous access. Although the antegrade approach is much more commonly performed, a retrograde approach may be selected when the surgeon has limited experience with antegrade percutaneous renal puncture or in situations where there might be a technical advantage to the retrograde approach, such as morbid obesity or a hypermobile or abnormally situated kidney (Mokulis and Peretsman, 1997). The Lawson Retrograde Nephrostomy Wire Puncture Set (Cook Urological, Spencer, IN) is the device commercially available for this approach. The fundamental maneuver of this procedure is to pass a stiff wire from inside the kidney toward and through the external body wall. This can be directed

Figure 8-14. Retrograde percutaneous access. A, Torcon deflectable catheter. B, Assembled unit passing puncture needle out through the abdominal wall and skin.

fluoroscopically or under direct vision with ureteroscopy. For the former, pass a 7-Fr Torcon catheter (actively deflectable from 0 to 140 degrees; Fig. 8-14A) over a guidewire and direct it fluoroscopically into the targeted calyx. Insert the 3-Fr polytetrafluoroethylene (PTFE) sheath containing the 0.017-inch stainless steel puncture wire through the Torcon catheter. Advance the puncture wire through the kidney and body wall under fluoroscopic control, withdrawing and repositioning it if any obstacles such as a rib are encountered (Fig. 8-14B). Make a small skin incision and grasp the wire externally. Use the fascial dilators in an antegrade fashion until the Torcon catheter can be advanced through the tract. When the end of the catheter exits the skin, exchange the puncture wire for a standard 0.035-inch guidewire, thus attaining through-and-through access. This fluoroscopic technique is reported to be safe and effective (Sivalingam et al, 2013).

For the ureteroscopic approach to retrograde percutaneous access, direct the ureterscope into the desired calyx and pass the 0.017-inch stainless steel puncture within the 3-Fr PTFE sheath through the working channel. First described in 1989 (Munch, 1989), in more recent reports it has been suggested that urologists without training in percutaneous antegrade access may be able to adopt this technique more readily (Wynberg et al, 2012) and that this approach may be associated with shorter operation time and fewer complications compared to antegrade access (Kawahara et al, 2012). Further experience is required before the role of retrograde percutaneous access (whether fluoroscopically or ureteroscopically directed) can be ascertained.

Antegrade Approach to Access into the Collecting System: Needles and Guidewires

The antegrade approach to percutaneous access into the upper urinary tract collecting system is the standard. It affords the most control of the skin entry site and can be guided by ureteroscopy or a variety of imaging modalities.

Figure 8-15. Percutaneous access needle, with a blunt sheath and a sharp obturator.

The general scheme of antegrade access is to place a needle through the skin into the upper urinary tract collecting system. A guidewire is placed through the needle and then catheters and other devices are placed over the guidewire, eventually enlarging the tract until the desired lumen is reached for the purpose of the procedure. This is the Seldinger technique, described (for vascular access) by [Sven-Ivar Seldinger \(1953\)](#). The standard choices for the needle are a 21-gauge needle through which is passed a 0.018-inch guidewire or an 18-gauge needle through which is passed a standard 0.035-inch guidewire. Both needles have a blunt sheath and a sharp obturator ([Fig. 8-15](#)). The 21-gauge needle has the advantage of causing relatively minor injury as it is passed through tissue. Multiple passes can generally be made with little risk of hemorrhage from the needle itself; the option to place and replace the needle multiple times is advantageous because getting the tip of the needle into the right spot in the kidney is the most difficult aspect of percutaneous access into the upper urinary tract collecting system. The 18-gauge needle is more traumatic, and multiple passes should be avoided. The advantage of the 18-gauge needle is that it is stiffer. In a number of circumstances the 21-gauge needle does not adequately maintain trajectory (e.g., scarred kidney, obese patient) and the 18-gauge needle is more effective. In addition, the 0.018-inch guidewire that passes through the 21-gauge needle ([Fig. 8-16](#)) must be exchanged for a standard 0.035-inch guidewire for subsequent tract dilation or catheter placement. This requires an extra step, which adds to the complexity of the procedure and increases the risk of a loss of access. Balancing the reduced efficacy of the 21-gauge needle and its increased potential for loss of access, versus the increased risk of trauma with the 18-gauge needle, it is recommended that the 21-gauge needle be used when the operator is less experienced or if minimizing trauma is paramount. The 18-gauge needle should be used when an experienced operator is confident that the tip of the needle can be placed within the desired calyx with just a few attempts.

Two methods can be used to exchange the 0.018-inch for a 0.035-inch guidewire. A coaxial introducer incorporates a small catheter within a slightly larger catheter. After inserting the 0.018-inch guidewire and removing the needle, the coaxial introducer is advanced over the guidewire until the end is within the renal collecting system. The surgeon should remove the inner catheter and 0.018-inch guidewire and then should advance a 0.035-inch guidewire through the outer catheter into the collecting system. The second method uses a graduated introducer that fits over the 0.018-inch guidewire at its tip but then enlarges to a lumen that will accept the 0.035-inch guidewire. A few centimeters back from the tip is a hole through which the 0.035-inch guidewire can pass. After inserting the 0.018-inch guidewire and removing the needle, pass the graduated introducer over the guidewire until it is a few centimeters

Figure 8-16. A 0.018-inch guidewire passed through percutaneous needle. This wire is exchanged for a 0.035-inch guidewire for subsequent manipulation.

inside the kidney, such that the side hole is within the renal collecting system. Remove the 0.018-inch guidewire and then insert an angled or J-tipped 0.035-inch guidewire through the introducer until the end of the wire exits the catheter within the collecting system. With either the coaxial or graduated introducer, a stiffener can be used to assist in passing the device over the relatively insecure 0.018-inch guidewire.

The safest initial 0.035-inch guidewire to use for upper urinary tract percutaneous access is a PTFE-coated J-wire. The “J” tip makes the guidewire unlikely to perforate out of the collecting system. This guidewire will not easily pass down the ureter, however, which is more easily handled with a floppy-tip PTFE-coated guidewire or a hydrophilic guidewire with a straight or angled tip.

Antegrade Approach to Access into the Collecting System: Technique of Initial Access

The initial percutaneous access to the upper urinary tract collecting system described by [Goodwin and colleagues \(1955\)](#) was “blind.” In 1974 Pedersen first reported ultrasonographic guidance ([Pedersen, 1974](#)). Although “blind” access is still occasionally reported and in expert hands can be successful, in most cases the initial antegrade percutaneous access into the upper urinary tract collecting system is obtained with real-time imaging guidance. Ultrasonography and fluoroscopy are most commonly used, with the choice based on patient characteristics and physician preference ([Basiri et al, 2008a](#)). A large multi-institutional matched-case analysis did not show any differences between ultrasonographic and fluoroscopic guidance of percutaneous access for nephrolithotomy in terms of hemorrhage and treatment success ([Andonian et al, 2013](#)).

Ultrasonographic Guidance

Ultrasonography has the advantages of portability (the mobile ultrasound machine is easier to maneuver than a C-arm fluoroscopy unit and does not require a radiolucent operating table), the ability to assess intervening structures, and no delivery of ionizing radiation. In addition, retrograde injection of contrast material or air is not necessary because the collecting system can readily be distinguished within the kidney based on ultrasonographic appearance alone. The disadvantages of ultrasonography include less clear visualization of the percutaneous needle (although etched needles created for enhanced sonographic appearance are available), a limited field of view compared with fluoroscopy, and difficulty monitoring the subsequent steps of

Figure 8-17. Ultrasonographic guidance of puncture needle.

the procedure. Ultrasonography is the first choice in imaging when retrograde access cannot be attained or is difficult to attain, such as in kidneys above urinary diversions, transplanted kidneys, kidneys above a completely obstructed ureter, or when radiation exposure is a concern. Ultrasonography also may be useful in the setting of skeletal abnormalities or anomalous kidneys, when intervening anatomy may differ from the norm (Chen et al, 2013; Penbegul et al, 2013). When percutaneous access is necessary for simple drainage of the kidney, such that the exact site of access is not critical as long as puncture into the renal pelvis or an infundibulum is avoided, ultrasonography is more expedient and more convenient than fluoroscopy.

Using a handheld 3.5- or 5-MHz ultrasound transducer, inspect the kidney and select a calyx for percutaneous entry. Needle guides can be placed on the transducer to direct the needle in the plane of visualization of the probe. Some prefer to place the needle freehand instead, moving the transducer around to gain different views of the kidney and needle. Observe the needle as it is advanced until it appears that the tip is within the collecting system (Fig. 8-17). Removing the obturator and aspirating urine confirms entry. Saline infusion and furosemide administration may improve ultrasonographic visualization of a nondilated intrarenal collecting system (Yagci et al, 2013). In one nonrandomized comparison (Lu et al, 2010) and one randomized controlled trial (Tzeng et al, 2011), the addition of Doppler to ultrasound imaging (which facilitates visualization of blood vessels) was associated with less blood loss and/or lower transfusion rate than ultrasound alone.

Fluoroscopic Guidance

Fluoroscopic guidance is more commonly used for gaining antegrade access to the upper urinary tract collecting system for percutaneous renal surgery. Although retrograde instillation of air and/or contrast material is not absolutely essential (Tabibi et al, 2007), most urologists find that it enhances fluoroscopically guided percutaneous access (Fig. 8-18). Fluoroscopy provides excellent delineation of the intrarenal collecting system anatomy and pathology (when contrast-enhanced), a wide field of view (that can be collimated down to reduce radiation exposure), and the ability to monitor all steps of the procedure. In some cases combining the techniques is an excellent approach, using ultrasonography to guide the initial needle placement and then using fluoroscopy (after injection of air and contrast through the sonographically guided needle) to confirm that the desired calyx has been accessed and to monitor the subsequent steps of the procedure (Osman et al, 2005). If the entry site is incorrect, then fluoroscopy of the air-and-contrast-filled collecting system can be used to guide another needle into the desired calyx. With this combination, retrograde assistance is not necessary. A randomized controlled trial between percutaneous nephrolithotomy access directed only by fluoroscopy versus ultrasonography plus fluoroscopy showed fewer puncture attempts, shorter access time and reduced

Figure 8-18. Injection of air into contrast-filled upper tract collecting system shows posterior calyces, in this case most clearly the upper pole calyces. Compare with Figure 8-12, before injection of air.

fluoroscopy time in the ultrasonography-plus-fluoroscopy group, without differences in success rate or hemorrhage (Agarwal et al, 2011). This technique is especially useful in accessing nondilated systems without retrograde assistance (Patel and Hussain, 2004).

There are two well-described methods of fluoroscopic guidance for antegrade percutaneous access into the upper urinary tract collecting system: the “eye-of-the-needle” technique and the “triangulation” technique (Miller et al, 2007). Both have their proponents, and there is no clear advantage of one rather than the other, as confirmed by one randomized controlled trial (Tepeler et al, 2012). Through the retrograde device, inject contrast material to delineate the collecting system after first taking note of any radiopaque pathology for later reference. Comparing a spot film of the unopacified collecting system with the opacified view is useful in this regard. After the options for the calyces of entry are identified, inject air to define the calyces that are posterior. In the prone position, air rises up the posterior calyces. The “double-contrast” pyelogram (both contrast material and air) provides the best determination of the pertinent intrarenal anatomy.

To perform the “eye-of-the-needle” technique, first inspect the kidney with the fluoroscopy unit directly above the patient (directed vertically) and select the desired calyx. Next, rotate the top of the fluoroscopic unit 30 degrees toward the operator, which brings the fluoroscopic view more or less end-on with the posterior calyces. The unit can be additionally rotated slightly cephalad or caudad to line it up more exactly with the axis of the calyx. Place the tip of a hemostat on the skin and move it until it is directly over the desired calyx. Mark this site and make an incision large enough to accept the needle and initial dilators. Place the tip of the access needle into this incision, and then move the shaft of the needle while keeping the tip in place until the needle is directly in line with the axis of the fluoroscopy unit; doing so gives the appearance of a “bull’s eye” with the hub of the needle (appearing as a circle) around the shaft (which appears as a dot). The fluoroscopic view is as if the operator is looking down the shaft of the needle at the targeted calyx—thus

Figure 8-19. “Eye-of-the-needle” fluoroscopic guidance. **A,** With the top of the fluoroscopic unit rotated 30 degrees toward the operator, the needle is lined up directly over the intended calyx of entry. **B,** With the fluoroscopy unit rotated away from the operator, the needle is now seen in profile, and in the figure has already been advanced under fluoroscopic control to achieve collecting system entry.

the term “eye of the needle” (Fig. 8-19A). Advance the needle straight in, while checking with fluoroscopy and adjusting the angle of the needle as needed to maintain the “bull’s-eye” appearance. If the needle is more than a few centimeters deep and readjustment is necessary, the needle may have to be withdrawn before a new trajectory can be followed. The 21-gauge needle can be difficult to control during this step. If difficulty occurs, substitute the more easily passed 18-gauge needle. After the needle’s axis is fixed and it is thought that the needle is approaching or is in the kidney (typically a “pop” can be felt when the renal capsule is punctured), then rotate the fluoroscopy unit away from the operator, back to vertical or even 10 to 15 degrees beyond vertical. Now the needle appears “in profile” as a straight line. With the cephalo-caudad and mediolateral axes of the needle now fixed, advance or withdraw the needle to change its anteroposterior position (depth) to move the tip of the needle into the desired calyx (Fig. 8-19B). Aspiration of urine or air after removing the obturator confirms entry. Instillation of contrast material can be used to confirm entry as well, but if the needle is misplaced, the extravasated contrast material can obscure subsequent fluoroscopic visualization. If a gently passed guidewire stays within the contours of the collecting system, then this confirms proper entry without risking the troublesome extravasation of contrast material.

To use the “triangulation” technique, inspect the kidney with the fluoroscopy unit directly above the patient to select the desired calyx, and hold the needle in the approximate position of the

desired angle of entry. Rotate the top of the fluoroscopy unit cephalad and lateral, and widen the field of view with the collimator such that mediolateral (left-right) movements of the needle are apparent. Move the shaft of the needle while keeping its tip in place until the needle is aimed toward the desired calyx (Fig. 8-20A). Then rotate the top of the fluoroscopy unit medially 45 degrees. While keeping the mediolateral orientation of the needle constant, move the needle in the cephalo-caudad (up-down) plane until the needle is again aimed toward the desired calyx (Fig. 8-20B). Resting the forearm on the patient’s back will help stabilize the needle in one plane while moving in the other. Move the fluoroscopy unit back and forth between these two positions until the needle remains aimed at the desired calyx on both views. Advance the needle under fluoroscopic guidance while monitoring the anteroposterior direction (depth) of the needle tip. If the needle position in the mediolateral and cephalo-caudad planes is maintained, the needle should enter the targeted calyx.

With the “eye-of-the-needle” technique, the proper cephalo-caudad and mediolateral axes of the needle are verified and maintained on a single fluoroscopic view, and the confirmatory view is necessary only to assure the depth of the needle tip. For the “triangulation” technique, one fluoroscopic view is used to assess the mediolateral axis and another is used to assess the cephalo-caudad axis, with the depth of the needle tip being assessed on both views (Miller et al, 2007). The advantage of the triangulation technique instead of the “eye-of-the-needle” technique is that the needle

Figure 8-20. Triangulation fluoroscopic guidance. **A**, With the top of the fluoroscopy unit rotated laterally and cephalad, adjust the access needle (arrows) to a mediolateral orientation of the needle. **B**, After rotating the top of the fluoroscopy unit medially, and while keeping mediolateral orientation of the needle constant, move the needle in the cephalo-caudad plane until the needle is again aimed toward the desired calyx. (From Miller NL, Matlaga BR, Lingeman JE. Techniques for fluoroscopic percutaneous renal access. *J Urol* 2007;178:15–23.)

cannot be passed too deeply because the depth of advancement is monitored continuously. The disadvantage of the “triangulation” technique is that maintaining both the mediolateral and cephalo-caudad planes is difficult because both are not being monitored at the same time, as in the “eye-of-the-needle” technique. Use of the 18-gauge rather than a 21-gauge needle is recommended with the “triangulation” technique to help maintain the angle of entry. Mechanical devices that stabilize the needle during insertion might be helpful as well (Lazarus and Williams, 2011).

It should be remembered that the ionizing radiation presents a small but real risk. When the operator must grasp the access needle within the fluoroscopy field, it is best to hold the needle with a hemostat, sponge forceps, or purpose-built needle holder to reduce radiation exposure to the operator’s hand. Collimating the field down as much as possible while still maintaining an adequate field of view reduces radiation exposure to the patient and all personnel in the room. Moving a collimated field around to maintain the object of interest in the field is preferable to maintaining a wide field that includes the operator’s hands and unnecessary body parts of the patient. Increased body mass index, greater stone burden, nonbranched stones, a greater number of access sites, and the use of air rather than contrast during initial retrograde pyelography are associated with an increased radiation dose (Mancini et al, 2010; Lipkin et al, 2011). For additional information about radiation safety, see Chapter 2.

Advanced Guidance

In some complex cases, one might consider percutaneous access into the kidney guided by CT or MRI. The initial access is obtained into the desired calyx with the patient on the CT or MRI table, similar to the techniques used for needle biopsy (Barbaric et al, 1997; Hagspiel et al, 1998; Thanos et al, 2006). Bowel and other viscera can be imaged to protect against their injury, and this approach is especially useful in cases of anatomic abnormalities (LeMaitre et al, 2000; Matlaga et al, 2003; Srivastava et al, 2010) and for nondilated collecting systems (Merkle et al, 1999; Egilmez et al, 2007; Sommer et al, 2011).

A stereotactic fluoroscopy technique using three-dimensional coordinates for localization was reported as associated with greater accuracy and lower blood loss compared to standard fluoroscopy (Li et al, 2012a). The same principle can be computerized, as demonstrated in an experimental ex vivo model (Zarrabi et al, 2010).

An even more advanced modification of fluoroscopy is three-dimensional fluoroscopy, which provides images with a level of quality equivalent to CT. Application to percutaneous access of porcine kidneys appeared to be effective (Soria et al, 2009), and a clinical series has suggested potential benefits (Roy et al, 2012).

Three-dimensional ultrasonography accurately represents the renal collecting system (Ghani et al, 2008) and appears useful for renal imaging (Kim et al, 2008) and for teaching percutaneous access into an in vitro renal model (John et al, 2009). Given that three-dimensional ultrasonography has been applied to other therapeutic urologic applications (such as percutaneous drainage of prostatic abscesses) (Varkarakis et al, 2004), investigation of its use for clinical percutaneous access of the collecting system is anticipated.

Imaging modalities can also be combined. There has been one report of a novel image localization system that projects the ultrasonographic puncture tract onto the fluoroscopy screen (Mozer et al, 2007). Preoperative MRI data can be merged with intraoperative ultrasonography to improve puncture accuracy (Li et al, 2012b). More frequently reported is the integration of preoperative CT images with intraoperative ultrasonography (Leroy et al, 2004; Mozer et al, 2005; Wein et al, 2008).

In addition to advanced image guidance of percutaneous access to the intrarenal collecting system, technologic enhancements have been applied to the initial needle puncture. The URrobotics Laboratory at Johns Hopkins University has developed the robotic percutaneous access to the kidney with remote center of motion device (PAKY-RCM) (Cadeddu et al, 1997b). This is a robotic arm with 7 degrees of freedom that places a needle into the intrarenal collecting system as directed by the control device that pivots the tip of the needle about a fixed point on the skin. In a nonrandomized clinical trial, the PAKY-RCM system was equivalent to an expert physician in gaining access to the collecting system in terms of time and accuracy (Su et al, 2002). In a randomized trial in an in vitro kidney model, the PAKY-RCM took slightly more time but was more accurate than manual needle insertion (Challacombe et al, 2005b). This device can also be controlled at distance with telepresence technology (Bove et al, 2003; Netto et al, 2003). The same group subsequently developed a robot for percutaneous access that is MRI-compatible (Mozer et al, 2009). Percutaneous access needles incorporating advanced characteristics such as piezoelectric crystals that allow the needle to be adjusted for particular orientations (Yan et al, 2007), electromagnetic sensors that provide real-time

information of position and orientation (Yaniv et al, 2009; Huber et al, 2011; Rodrigues et al, 2013), and impedance-based sensing systems to detect entry into the collecting system have also been developed (Hernandez et al, 2001; Roberts et al, 2002), but clinical use for percutaneous intrarenal surgery has not been reported. The “all-seeing needle” consists of a modified percutaneous access needle with 1.6-mm (4.85-Fr) outer diameter through which is inserted micro-optics (0.9-mm diameter) coupled to a zoom ocular that allows visualization of the needle access tract during initial entry (Bader et al, 2011). Clinical application has been reported and appears to be favorable. Finally, Rassweiler and associates (2012) have described an “augmented reality” application of an iPad combined with CT images obtained with markers, integrating radiographic and visual information, to direct percutaneous renal access.

“Blind” Access

The upper urinary tract collecting system can also be accessed “blindly,” without any imaging guidance (Chien and Bellman, 2002). The only situation in which this should be considered is when sonography is not available and there is complete ureteral obstruction (precluding retrograde instillation of contrast material or opacification of the collecting system with intravenous contrast). The lumbar notch, also known as the *superior lumbar triangle* or *Grynfeltt lumbar triangle*, has been reported as a reliable landmark for blind percutaneous renal access (Fig. 8-21). The lumbar notch is an area of muscular insufficiency through which hernias can occur. It is located posteriorly below the 12th rib. The superior border is the 12th rib and the latissimus dorsi muscle, the lateral border is the transversus abdominis and external oblique muscles, the medial border is the quadratus lumborum and sacrospinalis muscles, and the inferior border is the internal oblique muscle. Insert a needle 3 to 4 cm deep into the notch at a 30-degree cephalad angle to enter the collecting system. Another blind approach to the collecting system is to insert a needle directly perpendicular to the body surface 1 to 1.5 cm lateral to the L1 vertebral body, which

will lead directly to the renal pelvis if anatomy is normal. If fluoroscopy is available, then air and contrast material can be injected through a blindly placed needle to assess fluoroscopically its position and to guide another needle if needed. In the only randomized clinical trial comparing “blind” access to image-guided access, entry into the collecting system was successful in 50% and 90% of cases, respectively (Basiri et al, 2007). Use of the technique is not recommended in most settings.

Working Access

After good access to the collecting system is attained, exchange the initial guidewire through a catheter for a different one as needed. Dilate the tract over the guidewire with stiff plastic dilators or a metal fascial cutter to enlarge the tract to 8 to 12 Fr. If the goal of the procedure is simple drainage, then a small-caliber nephrostomy tube can be placed over the single guidewire to complete the procedure.

Safety Wire

If ureteroscopic assistance is used, the first guidewire inserted into the kidney can be grasped with the ureteroscope and pulled down the ureter and out the external urethral meatus. With this through-and-through access, the guidewire cannot be lost. **In all other situations, the goal for a therapeutic percutaneous procedure is to move two guidewires down the ureter into the bladder, generally a super-stiff (working) guidewire and a floppy-tip or J-tipped PTFE-coated (safety) guidewire.** One important exception is in cases where a dependent lower pole has been accessed percutaneously. If there is extreme angulation to get from the lower pole calyx to the ureteropelvic junction and down the ureter, placing a super-stiff guidewire down the ureter may put undue force on the kidney and risk tearing the parenchyma. In such cases, the flexible safety guidewire should still be directed down the ureter if possible, but the stiff working wire over which the dilation is performed can

Figure 8-21. The lumbar notch is a useful anatomic landmark for blind percutaneous access to the renal collecting system. It is bounded superiorly by the latissimus dorsi muscle and the 12th rib, medially by the sacrospinalis and quadratus lumborum muscles, laterally by the transversus abdominis and external oblique muscles, and inferiorly by the internal oblique muscle.

Figure 8-22. A, Kumpé catheter placed through the outer sheath of a coaxial catheter and manipulated toward the ureteropelvic junction helps direct a guidewire (B) down the ureter.

simply be directed toward the upper pole. Additionally, in some cases the pathology (e.g., calyceal obstruction, impacted ureteral stone, large staghorn stone) prevents the surgeon from getting a guidewire down the ureter or even into the remainder of the intrarenal collecting system. In such cases attempts should be made to move as much guidewire as possible into the upper urinary tract collecting system. A guidewire with a moveable core is useful in this setting because it can be coiled more tightly.

There are several techniques for inserting a guidewire down the ureter. The safest maneuver is to place a stiff angled-tip hydrophilic guidewire adjacent to the initial stiff angled-tip hydrophilic guidewire using a coaxial or dual-lumen catheter. Remove the coaxial or dual-lumen catheter and place an angled-tip catheter (Kumpé, Cobra, or coudé tip) over the angled-tip hydrophilic guidewire to help direct it down the ureter. After the stiff angled-tip hydrophilic guidewire is down the ureter, optimally all the way into the bladder, use the coaxial or dual-lumen catheter to place a second guidewire down the ureter. In cases of secure access, the initial wire can be exchanged for a stiff angled-tip hydrophilic guidewire through an angled-tip catheter to pass down through the ureter quickly (Fig. 8-22); alternatively, the surgeon can use a stiff angled-tip hydrophilic guidewire as the initial wire.

Dilation of Tract

After there is adequate wire access into the upper urinary tract collecting system, dilate the tract to allow insertion of working instruments. In most cases the goal of dilation for percutaneous renal surgery is to place a 30-Fr inner-diameter/34-Fr outer-diameter plastic access sheath. In some cases a smaller sheath, with an inner diameter measuring 12- to 24-Fr, is adequate. Renal access sheaths generally have a beveled tip, such that one side of the sheath extends farther than the other part. This bevel is used to maintain access into part of the collecting system on one side of the sheath while allowing extra mobility on the other side. Sheath repositioning is facilitated by the bevel. In cases of pathology at the edge of the collecting system, however, the bevel presents a disadvantage because the entire tip of the sheath cannot be placed into the collecting system. Both opaque and clear sheaths are available; some prefer the clear sheaths because structures next to the sheath can be visualized.

In the early years of therapeutic percutaneous renal procedures, the tract was dilated gradually through the course of many days by placing sequentially larger tubes. Castañeda-Zúñiga and associates (1982) first reported acute dilation of the tract. There are several dilator systems available. Regardless of the method used, it is imperative that the dilator does not pass too far into the

Figure 8-23. Alken guide rod is positioned with the ball at the tip of the rod positioned at the intended depth of the dilation.

collecting system. If this occurs, an infundibulum, the renal pelvis, or the ureteropelvic junction can be torn or perforated, either directly by the dilator or indirectly by a stone pushed aside by the dilator. The dilator should be passed just into the calyx. It is better to dilate a bit “short” of the targeted calyx than to dilate too far, which would create trauma. The initial inspection with the nephroscope confirms entry of the sheath into the calyx. If the sheath is not deep enough, then simply replace the dilating device and redilate after advancing the device. The dilators should not be used to dilate the skin; the skin should be incised to allow entry of the final sheath without pressure on the skin edges.

Sequential rigid metal dilators, introduced by Alken (1985), are a series of progressively enlarging coaxial stainless steel rods that pass over an 8-Fr guide rod. The first step in tract dilation is to pass the 8-Fr guide rod over a 0.035-inch guidewire. The end of the guide rod has a ball that prevents advancement of the first dilating rod beyond the tip. The ball is positioned at the intended depth of the dilation (Fig. 8-23). After passing the first rod, each successive metal rod is passed sequentially over the former until the desired tract is achieved, up to a 30-Fr rod over which is passed a 30/34-Fr plastic

Figure 8-24. Amplatz dilators with sheaths.

Figure 8-25. Balloon dilation catheter with preloaded sheath.

sheath. The advantages of the rigid metal dilator system are that it is the most effective dilator, able to dilate even when there is dense perirenal scarring from previous procedures, and that it is inexpensive on a per-case basis because it is reusable. The disadvantage is that, for the same reason they are so effective, the rigid metal dilators can do considerable damage. The depth of the dilation can be difficult to maintain accurately, especially when pushing against tough scar tissue. One group has modified the rigid metal rods, tapering the ends and adding centimeter markings (Shen et al, 2007).

Progressive semirigid plastic dilation sets (often referred to as “Amplatz” dilators after Kurt Amplatz, the senior author in the initial publication [Rusnak et al, 1982]) consist of progressively larger firm plastic (polyurethane) dilators that are passed over an 8-Fr PTFE guiding catheter that fits over a 0.035-inch guidewire (Fig. 8-24). The dilators are passed one after the other, not coaxially like the rigid metal dilators but progressively, advancing one dilator, removing it, advancing the next largest dilator, and so on until the final tract diameter is achieved. The working sheath is passed over the final dilator and then the dilator and 8-Fr catheter are removed, leaving the working wire and sheath in place. The dilators are made in increments of 2 Fr, but if the tissue being dilated is soft, then not every dilator needs to be used. The advantage of the semirigid plastic dilation system is that trauma to the collecting system is theoretically less likely than with the rigid metal dilators (although experienced urologists have found no difference between the two systems in terms of safety), but the disadvantage is that hemorrhage can occur each time a dilator is withdrawn. Current semirigid plastic dilators are sold as disposable devices, so they are more expensive on a per-case basis than rigid metal dilators. One retrospective comparison of the two techniques showed no other differences (Ozok et al, 2012).

Balloon dilators (Fig. 8-25) were developed to obviate the repetitive dilations of the rigid metal and semirigid plastic dilation systems, which are both time consuming and potentially dangerous. This is the most common dilation method for percutaneous renal surgery today (Benway and Nakada, 2008). The appropriate working sheath is back-loaded onto the balloon dilation catheter, which is passed over the working wire until the radiopaque marker is at the intended depth of dilation (Fig. 8-26A). The dilating balloon is inflated with a pressure syringe. A “waist” appears at the site(s) of greatest resistance, usually the abdominal wall fascia and the renal capsule (Fig. 8-26B). After the balloon is fully expanded (Fig. 8-26C), the working sheath is passed over the balloon (Fig. 8-26D) (Fig. 8-27 on the Expert Consult website). The balloon catheter has a “shoulder,” which is the portion between the end of the balloon and the point at which the maximal diameter is achieved. The sheath should not be passed beyond the maximal diameter of the balloon because this can cause significant injury.

Balloon dilators, which are expensive one-time-use devices, are less effective than rigid metal and semirigid plastic dilation systems in densely scarred tissue but are more effective when the kidney is hypermobile (Kumar and Keeley, 2008). Most (Heggagi et al, 1991; Davidoff and Bellman, 1997; Safak et al, 2003; Kukreja et al, 2004), but not all (Gonen et al, 2008a; Wezel et al, 2009), single-series reports have suggested that hemorrhage and transfusion rates are less with the balloon dilators compared with rigid metal and semirigid plastic dilators. In a large multi-institutional study, however, balloon dilation was associated with longer operative time and greater bleeding and transfusion rates compared to rigid metal and semirigid plastic dilators (Lopes et al, 2011). Baseline differences between the groups, including more stones per kidney and more frequent treatment of staghorn calculi in the balloon dilation, may have created bias against balloon dilation.

In an effort to simplify dilation of the renal access tract further, a number of single-step techniques have been described. The simplest is passage of the final semirigid plastic dilator without previous dilation by the smaller dilators (Frattini et al, 2001). A meta-analysis of 4 randomized controlled trials comparing a single plastic dilator with sequential rigid metal dilators suggested that the former was associated with reduced access and fluoroscopy times without increased complications (Li et al, 2013b). Devices designed specifically for single-step dilation include a balloon dilator with an expandable sheath (Pathak and Bellman, 2005; Baldwin et al, 2006; Maynes et al, 2008; Kalpee et al, 2012) and a rigid dilator with an expandable sheath (Goharderakhshan et al, 2001). Preliminary results with these devices appear favorable.

The most common cause of difficult tract dilation is previous renal surgery (Joel et al, 2005). Densely scarred kidneys present a challenge. Even if semirigid plastic or rigid metal dilators fail, novel uses of devices such as Collings knives and atherotome cutting balloons can be used (Davis et al, 1991; Williams et al, 2008). One group has reportedly used a bipolar resectoscope with a plasma vaporization electrode to enlarge the percutaneous tract, and in their randomized controlled trial there were some advantages over balloon dilation (Chiang et al, 2013).

Modifications in Special Situations

In cases of anomalous kidneys (malrotated, ptotic, ectopic, horseshoe, and other fused kidneys), alteration of the percutaneous approach to the upper urinary tract collecting system may be necessary. As noted earlier, in some situations real-time guidance of the needle puncture with CT or MRI might be considered, and ultrasonographic guidance may be useful, but in most cases preoperative CT or magnetic resonance suffices. Because the orientation of some organs might change with patient position, imaging in the intended position of surgery might be useful. Preoperative cross-sectional imaging of anomalous kidneys helps plan patient position, choice of calyx, and orientation of the tract, taking into account distance of the kidney from the skin, calyceal orientation, vascularity, and the relative orientation of adjacent organs.

Horseshoe kidneys frequently require percutaneous intervention. Although antegrade access into horseshoe kidneys is

Figure 8-27. Working sheath is passed over dilating balloon in lower pole access site. The working and safety guidewires both go down the ureter.

Figure 8-26. Balloon dilation of tract and placement of working sheath. **A,** Balloon catheter is inserted over wire, with distal radiopaque marker at the intended depth of dilation. **B,** “Waist” appears as balloon is inflated. **C,** Balloon is fully expanded. **D,** Sheath is passed over balloon, taking care not to advance it beyond the point of maximal diameter of the balloon.

somewhat different than into normal kidneys, standard techniques can generally still be used. CT or MRI should be considered for preoperative assessment of horseshoe kidneys, both to assess for the possibility of retrorenal colon ([Skoog et al, 1985](#)) and to assess the vasculature and relationship of the calyces to the anticipated puncture site. In a series of 12 patients undergoing percutaneous nephrolithotomy in horseshoe kidneys, 5 had bowel posterior to the kidney on CT ([Al-Otaibi and Hosking, 1999](#)). Horseshoe kidneys often have extra and eccentric calyces that can be difficult to access. In other ways, however, percutaneous access to a horseshoe kidney is more favorable than in normal kidneys. The anteroposterior tilt of the kidney is prominent, which makes the upper pole the most superficial and posterior aspect of the horseshoe kidney. In addition, the upper pole is usually inferior to the ribs. Upper pole access is useful in horseshoe kidneys because this is the easiest calyx to enter, the puncture rarely needs to be supracostal, and it provides excellent access to most of the kidney and the ureter owing to the alignment of the long axis of the moiety ([Fig. 8-28](#)). The initial entry into a horseshoe kidney is more medial than in normal kidneys and can pass through the paraspinous musculature. The distance to the lower pole and ureter can be great in an obese or muscular patient, such that extra-long rigid nephroscopes or flexible nephroscopy may be necessary. In some cases, middle calyceal access is preferred because the upper pole is so far away from the pathology, but lower pole calyces are usually not safely accessible with direct percutaneous puncture. The vasculature of

horseshoe kidneys is aberrant, but vessels enter and exit the kidney in an anteromedial location (except for some at the isthmus), so direct vessel injury is rare with well-planned access ([Janetschek and Kunzel, 1988](#)). Overall, among a total of 256 percutaneous procedures (primarily nephrolithotomy) recently reported in horseshoe kidneys, there were 11 (4.3%) major hemorrhagic complications and only 1 (<0.4%) colon injury ([Al-Otaibi and Hosking, 1999](#); [Shokeir et al, 2004](#); [Lojanapiwat, 2005](#); [Darabi Mahboub et al, 2007](#); [Mosavi-Bahar et al, 2007](#); [Viola et al, 2007](#); [Majidpour and Yousefinejad, 2008](#); [Miller et al, 2008](#); [Symons et al, 2008](#); [Gupta et al, 2009](#)).

Another way to access anomalous kidneys is with an anterior approach using laparoscopic assistance. This is most applicable to pelvic ectopic kidneys because a posterior approach is often blocked by the bony pelvis, although laparoscopic assistance has been used for percutaneous nephrolithotomy of a large calculus in an anteriorly directed calyx in the isthmus of a horseshoe kidney ([Maheshwari et al, 2004b](#)) and a large calculus in an anterior diverticulum of a horseshoe kidney ([Wong and Zimmerman, 2005](#)). The bowels can be mobilized off the surface of the kidney laparoscopically, and the access needle is passed through the anterior abdominal wall into the kidney under vision from the laparoscope. Retrograde assistance is still desirable because opacifying the collecting system assists in simultaneous fluoroscopic confirmation of calyceal entry and wire passage. Dilation and sheath insertion can be assessed both laparoscopically and fluoroscopically. In a

Figure 8-28. Percutaneous access sheath (radiolucent except for a radiopaque stripe) in upper pole of horseshoe kidney. Note medially directed lower pole calyx. Although not apparent from this radiograph, the access site is subcostal.

series of 12 laparoscopically directed antegrade percutaneous nephrolithotomies into pelvic kidneys published since 2001 that described a total of 35 patients, all procedures were reported to be successful and without complications (Troxel et al, 2002; Maheshwari et al, 2004a; Santos et al, 2004; Aron et al, 2005b; Aquil et al, 2006; Goel et al, 2006; Matlaga et al, 2006; El-Kappany et al, 2007; Mousavi-Bahar et al, 2008; Gupta et al, 2009; Tahmaz et al, 2009; Tepeler et al, 2013). As a simpler alternative to laparoscopic assistance, anterior percutaneous access into pelvic kidneys using a supine oblique position with a pad under the ipsilateral hemipelvis, as well as using ultrasonography to assess for intervening bowel, has been reported to be a safe technique in selected patients (Desai and Jasani, 2000; Mosavi-Bahar et al, 2007). If bone does not intervene between the appropriate calyx and the skin, then a posterior approach can be used just above the iliac bone (Atmaca et al, 2007) or through the greater sciatic foramen (Watterson et al, 2001).

Transplanted kidneys also mandate changes in the approach to percutaneous access of the upper urinary tract. The transplanted kidney, typically positioned extraperitoneally in the iliac fossa, has variable angles of the calyces depending on the placement of the kidney by the transplant surgeon. The usual approach is from the anterolateral direction, with the patient in the supine position. Percutaneous nephrostomy is the preferred approach to obstruction and for endoscopy of the collecting system in the transplant kidney (Mostafa et al, 2008). Ultrasonography is most convenient for initial access to the collecting system because retrograde assistance for fluoroscopy is difficult owing to the site and angle of the reimplanted ureter. Fluoroscopy can then be used as needed to facilitate subsequent steps. The dense fibrosis that often surrounds a transplant kidney can make dilation of the tract difficult, and semirigid plastic or rigid metal dilators may be necessary if balloon dilation fails. Of 75 percutaneous procedures in transplant kidneys reported in 10 recent series that used ultrasonographically and/or fluoroscopically directed percutaneous access, all but six were technically successful and there were no major complications (Francesca et al, 2002; Klingler et al, 2002; Challacombe et al, 2005a; He et al,

2007; Krambeck et al, 2008b; Rifaoglu et al, 2008; Wyatt et al, 2009; Oliveira et al, 2011; Stravodimos et al, 2012; Verrier et al, 2012).

KEY POINTS: OBTAINING PERCUTANEOUS ACCESS

- Optimally, the urologist is present at the time percutaneous access is attained, either performing the procedure or actively directing the radiologist.
- If there is increased likelihood of bacteriuria, preprocedure urine culture is recommended. Perioperative antimicrobial prophylaxis is recommended in all cases.
- Except for aspirin in some cases, oral anticoagulant or antiplatelet activity medications should be discontinued before percutaneous renal surgery.
- Preoperative cross-sectional imaging of complex cases, especially anomalous kidneys, helps plan patient position, choice of calyx, and orientation of the tract.
- Supine and flank positions offer some potential benefits over prone positioning in certain settings, but surgeon preference generally can determine the choice of position for percutaneous renal surgery.
- In the prone position, the preferred calyces are the posterior ones. Percutaneous access should never be directly into an infundibulum or the renal pelvis.
- An upper pole calyx is generally the most versatile site through which to enter the upper urinary tract collecting system.
- Subcostal access is the safest route to the kidney, but if entry directly above the 12th rib provides the best access to the optimal calyx, then the benefit generally exceeds the risk.
- Retrograde assistance facilitates antegrade access to the upper urinary tract collecting system.
- Ultrasonography and fluoroscopy are both commonly used to guide percutaneous access to the intrarenal collecting system. A useful combination is ultrasonography to guide the initial needle placement, which is followed by fluoroscopy to confirm that the desired calyx has been accessed and to direct and monitor the subsequent steps of the procedure.

POSTPROCEDURAL NEPHROSTOMY DRAINAGE

The final surgical consideration after percutaneous renal surgery is deciding which drain(s), if any, to insert into the upper urinary tract collecting system. Options include an externalized nephrostomy tube or nephroureteral stent, an internal or externalized ureteral stent, or no drainage tube at all. Additional discussion of these options can be found in Chapter 6.

Nephrostomy Tube

For years, the standard drainage after percutaneous surgery of the upper urinary tract collecting system has been an externalized nephrostomy tube. There are a variety of choices for postoperative nephrostomy tubes.

Balloon Catheters

The Foley and Councill catheters used for transurethral drainage can be used as nephrostomy tubes as well (Fig. 8-29). These tubes come in a range of diameters; typically 16- to 24-Fr catheters are used for postoperative nephrostomy drainage. The 5-mL retention balloon might be too large for some collecting systems and does not need to be completely inflated. The balloon can cause calyceal obstruction if it is pulled into an infundibulum. Saline or water should be used to inflate the balloon because viscous contrast material

might hinder emptying of the balloon when removal is attempted. An advantage of the Councill catheter is the ability to pass a small-caliber catheter through the end hole and down the ureter, providing more secure access to the upper urinary tract collecting system and maintaining ureteral patency. All nephrostomy tubes, even ones with robust internal retention devices, should be fixed to the skin externally with a suture or other mechanism. External fixation of a tube, however, does not necessarily prevent internal dislodgement of the tube. Especially in a large patient, the distance from the skin to the upper urinary tract collecting system can change with patient movement, and the tube (fixed at the skin) can pull out of the kidney. The potential for tube dislodgement is one of the best arguments in favor of nephrostomy tubes that have some extension down the ureter to maintain a conduit to the upper urinary tract collecting system, even if the renal pelvic portion of the tube is pulled out of the kidney.

Malecot Catheter

The wings of the Malecot catheter expand when the catheter is at rest, providing a modest but atraumatic and nonobstructive

Figure 8-29. Councill catheter.

retention mechanism (Fig. 8-30A). When the catheter is being placed or removed, a stiffener is inserted through it to push on the distal end of the Malecot tip and straighten the wings. During removal this stiffener can misalign with the Malecot tip if the tube is not straight; pulling the catheter back until the tube is straight helps the stiffener line up properly. The Malecot catheter is also available with an extension that is directed down the ureter. This modification is called a “re-entry” catheter, because it simplifies placing a guidewire through the Malecot catheter and down the ureter into the bladder (Fig. 8-30B). The extension is long enough (18 cm) so that in most patients the Malecot tube can be withdrawn until the wings are externalized and a guidewire can be placed into the ureter. Malecot catheters for renal use are large-bore catheters, ranging from 16 to 30 Fr, although Malecot catheters as small as 8 Fr are available.

Cope Catheter

Cope nephrostomy tubes provide a more secure retention mechanism. A string exits the catheter a few centimeters from the distal tip and then re-enters the catheter near the tip (Fig. 8-31). Pulling on the string forms a secure coil that is not easily dislodged from the renal pelvis. The string is fixed at the external end of the tube with a locking mechanism or by wrapping it around the tube and fixing it in place with a rubber cuff. Cope catheters use the same coil shape used in pigtail ureteral stents. The active reinforcement of the coil strength by the string is thought to provide more secure retention than the passive coil of a pigtail, although one comparative study did not confirm this (Chuang et al, 2011), and as such Cope catheters have replaced pigtail catheters for most percutaneous uses. Cope nephrostomy tubes, ranging from 6 to 14 Fr in diameter, can be used for simple upper urinary tract drainage and instillation procedures, as well as after percutaneous surgery.

Nephroureteral Stent

The Cope retention mechanism is also used in nephroureteral stents. A nephroureteral stent has a renal coil like that of a Cope nephrostomy tube, but the tube continues on to a ureteral extension that travels down the ureter to end in a passive pigtail that rests in the bladder (Fig. 8-32). The ureteral portion can be the same diameter as the nephrostomy portion, or it can be narrower. A nephroureteral stent is passed percutaneously over a wire that ends in the bladder. After the end is coiled generously in the bladder, careful inspection of the fluoroscopy image shows the location of the side holes in the renal coil. By moving the catheter in and out while pulling on the string and rotating the external portion of the tube clockwise, the Cope retention coil is formed in the renal pelvis (Figs. 8-33 and 8-34 on the Expert Consult website) A nephroureteral

stent offers excellent control of the entire upper urinary tract, from renal pelvis to bladder, and is unlikely to become dislodged. Nephroureteral stents are available in diameters of 8.5 or 10.2 Fr, and the standard lengths (from renal to bladder coil) are 20 to 28 cm.

Circle Catheter

A final type of nephrostomy tube is the circle nephrostomy tube (Fig. 8-35), which is secure, easily exchanged, causes little trauma, rarely occludes, and provides excellent drainage and avenue for irrigation of the renal pelvis. The circle nephrostomy tube requires two percutaneous access sites to the kidney, and this tube is most useful when maintenance of two tracts is desired, such as for irrigation of the renal pelvis or if more than one access is necessary for second-look nephroscopy (Kim et al, 2005). After obtaining access at two distant calyces, a flexible nephroscope or flexible ureteroscope passed over one wire is used to grasp the wire coming from the other site. When the endoscope is withdrawn, the wire is now in position to guide placement of the circle nephrostomy tube. Radiopaque markers on the tube delineate the location of the

Figure 8-31. Cope catheter, with the retention string loosened for demonstration.

drainage holes, which should be maintained within the intrarenal collecting system. External drainage of the circle nephrostomy tube requires a Y-connector.

General Considerations

The advantages of a postoperative nephrostomy tube include good drainage and control of the upper urinary tract, and maintenance of percutaneous access for additional procedures. It was initially thought that a postoperative nephrostomy served to tamponade the nephrostomy tract and reduce hemorrhage, but subsequent studies have suggested that this is not the case. When hemorrhage does occur, however, the larger caliber of a nephrostomy tube provides better drainage of the upper urinary tract collecting system than does an internal ureteral stent. In addition, if a large perforation has occurred during the procedure, the additional diversion of urine away from the site might be advantageous. When a nephrostomy tube is left in place following percutaneous renal surgery, it is usually in the dilated access site. At least one group has attempted to reduce the discomfort associated with supracostal percutaneous renal surgery by placing a small-caliber postoperative nephrostomy tube in a new subcostal site and leaving the dilated supracostal access site without a nephrostomy tube (although there was no control cohort for comparison) (Kim et al, 2006).

Along with the nephrostomy, including a tube that goes down the ureter provides the greatest control and assurance of drainage. Because entry of a tube into the bladder is associated with additional symptoms, however, such a tube should only be used when needed. Considerations include the size of the patient (which determines to a large extent the risk of tube dislodgement), the importance of maintaining drainage, and the desire for ureteral intubation (e.g., ureteral obstruction that might resolve if intubated, ureteral injury that should be bypassed). Aside from the choice of retention mechanism, the main remaining consideration is the diameter of the nephrostomy tube.

A number of studies have compared the impact of nephrostomy tube diameter after percutaneous renal surgery, including two nonrandomized prospective trials (Maheshwari et al, 2000; De Sio et al, 2011) and four randomized controlled trials comparing

Figure 8-32. Nephroureteral stent. A, Renal coil. B, Bladder coil.

Figure 8-35. Circle nephrostomy tube.

large-caliber tubes (20 to 24 Fr) to small-caliber tubes (8 to 18 Fr) (Liatsikos et al, 2002; Pietrow et al, 2003; Desai et al, 2004; Marcovich et al, 2004). Among the six studies, comprising a total of 215 patients with nephrostomy tubes, five showed less pain and two reported less urinary leakage in the patients with smaller tubes. Bleeding did not increase in any of the studies for the groups with smaller tubes. Only one study showed no benefit to the smaller tube (Marcovich et al, 2004). Although tube diameter is not related to bleeding overall, the removal of larger tubes occasionally can be followed by immediate hemorrhage; this is rare with smaller tubes. As such, large-caliber nephrostomy tubes should be removed in a radiology suite where there is the opportunity for immediate replacement of the tube. Small-caliber tubes can be removed safely at the bedside after a period of clamping to assess clinically for distal ureteral obstruction.

“Tubeless” with Ureteral Stent

Wickham and colleagues (1984) initially proposed a “tubeless” percutaneous procedure—one that omits the postoperative nephrostomy tube. This practice never met with widespread acceptance, especially after Winfield and colleagues (1986) reported disastrous outcomes with this technique. The concept was revived in 1997 by Bellman and colleagues (1997), with the addition of an internal ureteral stent left in place for a week or two. Since then, many studies have evaluated the practice of omitting the nephrostomy tube after percutaneous renal surgery. Although this technique is called “tubeless,” most series employ a ureteral stent for a short period postoperatively.

Options for ureteral stenting without a nephrostomy tube after percutaneous renal surgery include an internal ureteral stent that is removed cystoscopically, an internal ureteral stent with an attached string that exits out the flank to allow removal of the ureteral stent without cystoscopy, and an externalized (out the urethra) ureteral stent that is removed along with the urethral catheter to which it is attached. The potential advantages of omitting the nephrostomy tube after percutaneous renal surgery include decreased pain and analgesic use, avoidance of an external drainage device, abbreviated hospital stay, and decreased health care costs (secondary to shortening the duration of hospitalization). Since the report of Bellman and colleagues (1997), many studies including several randomized controlled trials have evaluated the omission of a nephrostomy tube postoperatively with the placement of an internal ureteral stent. It is important to note that most of these studies excluded patients with significant bleeding or perforation or those for whom a second percutaneous procedure was anticipated.

A meta-analysis of tubeless percutaneous nephrolithotomies published in 2012 included 9 randomized controlled trials involving 547 patients (Shen et al, 2012). The results were stratified into 4 groups relative to the postprocedure drainage: tubeless with internal ureteral stent, small nephrostomy tube (8 to 9 Fr), medium nephrostomy tube (16 to 18 Fr), and large nephrostomy tube (20 to 24 Fr). The meta-analysis demonstrated that hospital stay and postoperative pain were reduced in the tubeless group compared to the medium and large tube groups, but were similar in the tubeless and small tube groups. There were no significant differences between the tubeless group and any of the nephrostomy tube groups with regard to fever/infection, transfusion, or operative time. In two earlier meta-analyses that combined the nephrostomy groups into two instead of three groups, 4 to 10 Fr versus 14 to 24 Fr (Yuan et al, 2011) and 8 to 9 Fr versus 14 to 26 Fr (Ni et al, 2011), shorter hospital stay and reduced postoperative pain were noted in the tubeless groups even in comparison to the small nephrostomy group. Thus the preponderance of evidence suggests that **tubeless percutaneous nephrolithotomy leads to shorter hospital stay and reduced postoperative pain in comparison to use of large post-procedure nephrostomy tubes, but that these benefits are less certain in comparison to small nephrostomy tubes.** Subsequent randomized controlled trials (Kara et al, 2010; Etemadian et al, 2011; Marchant et al, 2011; Shoma and Elshal, 2012; Lu et al, 2013) and one large multi-institutional matched case-control study involving 488 patients (Cormio et al, 2013) have yielded similar results with the exception of one study that indicated no benefit to the tubeless approach when the nephrostomy tube in the comparison group was removed the morning after the procedure (Mishra et al, 2010). This latter study was underpowered, however, with only 22 patients; all trends favored the tubeless group, but the differences did not reach statistical significance. In one randomized controlled trial, omission of the nephrostomy tube was associated with decreased cost (Feng et al, 2001). The tubeless approach appears to be safe even when supracostal access is used (Shah et al, 2006b; Jun-Ou and Lojanapiwat, 2010; Duty et al, 2013) and in the setting of bilateral simultaneous procedures (Gupta et al, 2003; Shah et al, 2005).

There are some disadvantages to using an internal ureteral stent as an alternative to a nephrostomy tube, however, including loss of the percutaneous tract for a secondary procedure and the cost, inconvenience, and discomfort associated with an internal ureteral stent that requires cystoscopic removal at a later date. To obviate the problems associated with the ureteral stent, several groups have offered alternatives including insertion of an externalized ureteral stent or insertion of an internal stent with an attached string that exits out the flank. In both cases the stent can then be removed before hospital discharge without an additional procedure. Goh and Wolf (1999) first reported the use of an externalized ureteral stent (single pigtail) as an alternative to a postoperative nephrostomy tube. Since then there have been a number of reports of this option (Lojanapiwat et al, 2001; Abou-Elela et al, 2007; Karami et al, 2007; Rana and Mithani, 2007; Al-Ba’adani et al, 2008) including three randomized controlled trials, one comparing an externalized ureteral stent to a large-caliber nephrostomy tube, which suggested a benefit in terms of reduced narcotic use and length of hospital stay (Tefekli et al, 2007), and two comparing internal and external ureteral stents, which showed no difference between the two techniques except for the association of the external stent with a lack of outpatient stent-related symptoms in one study (Gonen et al, 2009) and shorter hospital stay and less hematocrit drop in another study (Mercado et al, 2013). Shpall and colleagues (2007) described the modification of leaving the attached string on the stent and placing the stent “upside down” so that the string can exit the flank. They described removing the stent as an outpatient 3 and 12 days postoperatively, but since then others have reported removing the stent at the bedside on the first postoperative day (Berkman et al, 2008). Use of a Polaris Loop stent (Boston Scientific, Natick, MA) placed “upside down” offers less resistance at the time of removal (Fig. 8-36).

Figure 8-36. Use of a Polaris Loop stent (Boston Scientific, Natick, MA) placed “upside down.” An attached string is left exiting the flank, which allows removal of the stent without an additional procedure.

These modifications of nephrostomy tube omission avoid many of the disadvantages of an internal ureteral stent but still leave the problem of loss of access in case a secondary procedure is required. With improved endoscopes, better ancillary tools, and growing experience with percutaneous surgery, the need for secondary procedures is declining. In properly selected patients including those who do not for some other reason need external drainage (e.g., pyonephrosis, significant bleeding, significant collecting system injury) and those who are unlikely to need a secondary procedure, omission of the postoperative nephrostomy tube appears to be safe and effective.

No Drainage Tube

More recently, the idea of a “totally tubeless” percutaneous renal surgery, omitting both the nephrostomy tube and ureteral catheter, has been reintroduced. This can be considered in selected patients with low-volume stones, atraumatic single access, and no hemorrhage, perforation, or obstruction. A meta-analysis of five randomized controlled trials and four nonrandomized comparative studies comparing “totally tubeless” percutaneous nephrolithotomy to percutaneous nephrolithotomy with a postprocedure nephrostomy tube suggests that the “totally tubeless” approach reduces hospital stay, analgesic requirement, and time to return to normal activity without increasing complications (Zhong et al, 2013). A more pertinent comparison is “totally tubeless” versus internal stent without nephrostomy tube (“tubeless”); one retrospective nonrandomized comparison showed that the “totally tubeless” approach was associated with a longer hospital stay than the “tubeless” approach (Istanbulluoglu et al, 2010).

Adjuncts to Drainage without Nephrostomy Tubes

One of the concerns with any approach that omits the nephrostomy tube after percutaneous renal surgery is that of hemorrhage from the tract. Although the evidence from randomized controlled trials suggests that the size or presence of the nephrostomy tube does not affect the degree of postoperative bleeding, there is still a potential for dramatic bleeding after any percutaneous procedure—and such bleeding would be more problematic without a nephrostomy tube in place. Several groups have described adjuncts intended to enhance hemostasis of the percutaneous tract including placing a fascial suture (Li et al, 2011), direct monopolar cauterization of the tract (Mouracade et al, 2008; Chang et al, 2011), cryotreatment of the tract (Okeke et al, 2009), and

insertion/instillation of hemostatic agents into the tract including oxidized cellulose (Aghamir et al, 2006), gelatin sponge (Singh et al, 2008), gelatin granules plus thrombin (Lee et al, 2004b; Nagele et al, 2006; Li et al, 2011), fibrin glue (Noller et al, 2004; Gudeman et al, 2012), and collagen matrix coated with fibrin glue (Cormio et al, 2012). One nonrandomized comparison of percutaneous nephrolithotomy with and without electrode cauterization of the tract reported a lower blood transfusion rate in the first group (1.2% vs. 6.5%, respectively) (Jou et al, 2004). A nonrandomized comparison of tract cryotherapy without a nephrostomy tube in 30 patients versus a 24-Fr nephrostomy tube without tract cryotherapy in 30 patients suggested that there was shorter hospitalization and less hemorrhage and urine leakage in the patients treated with cryotherapy. The high rate of postoperative hemorrhage requiring angioembolization in the control group (13%) confounds the analysis (Okeke et al, 2009). There have been four randomized controlled trials of hemostatic adjuncts for percutaneous renal surgery without nephrostomy tubes, which compared patients managed without hemostatic adjuncts with those managed with gelatin sponge (Singh et al, 2008), oxidized cellulose (Aghamir et al, 2006), fibrin glue (Shah et al, 2006a), and collagen matrix coated with fibrin glue (Cormio et al, 2012). None of the three studies showed an impact of the adjunct on measures of hemostasis (postoperative hematocrit, hemorrhage, and/or blood transfusions). Narcotic use was less in the adjunct group in two of the three studies in which it was evaluated. Hospital stay and urinary leakage were each assessed in three studies, and each was improved in two studies. Some nonrandomized studies also have suggested a shortened hospitalization and/or reduced narcotic use after tract hemostatic maneuvers, but because improvements in hemostasis and urinary leakage are not consistently found, the mechanism for improvement in these secondary outcomes is not clear (Mikhail et al, 2003; Aron et al, 2004; Borin et al, 2005). Alternatives to local treatment of the tract include systemic enhancements to hemostasis. In one randomized trial, oral administration of the antifibrinolytic agent tranexamic acid was associated with less reduction in hematocrit and lower blood transfusion rate (Kumar et al, 2013). Overall, the usefulness of any of the adjuncts for tract hemostasis is not certain and further study is necessary.

KEY POINTS: POSTPROCEDURAL NEPHROSTOMY DRAINAGE

- The advantages of a postoperative nephrostomy tube include good drainage and control of the upper urinary tract, as well as maintenance of percutaneous access for additional procedures. Inclusion of an extension down the ureter provides the greatest control and assurance of drainage.
- Small-caliber nephrostomy tubes are associated with less pain than large-caliber nephrostomy tubes and are not associated with any increased hemorrhage.
- The use of a ureteral stent instead of a large-caliber nephrostomy tube is associated with reduced narcotic use and decreased length of hospitalization. The benefit of nephrostomy omission is less apparent when compared with a small-caliber nephrostomy. In properly selected patients, the use of a ureteral stent instead of a nephrostomy tube does not affect stone-free or complication rates.
- Options for ureteral stenting without using a nephrostomy tube afterward include an internal ureteral stent that is removed cystoscopically, an internal ureteral stent removed by a string exiting out of the flank, and an externalized ureteral stent that is removed along with the urethral catheter to which it is taped.
- Following straightforward procedures with atraumatic single access and no hemorrhage, perforation, or obstruction, some patients can be managed without a nephrostomy tube or a ureteral stent.
- The usefulness of adjuncts for tract hemostasis is uncertain.

TRAINING IN PERCUTANEOUS ACCESS AND PROCEDURES

Efforts to enhance training for percutaneous surgery of the upper urinary tract have focused on obtaining percutaneous access. Summarizing their own experience and other reports (Allen et al, 2005; Tanriverdi et al, 2007), de la Rosette and colleagues (2008) estimated that a trainee must perform approximately 24 percutaneous nephrolithotomies to attain proficiency, whereas competence is not achieved until the experience includes 60 cases, and excellence is not obtained until more than 100 cases have been performed. The American College of Radiology's "Practice Guideline for the Performance of Percutaneous Nephrostomy" recommends that a physician must have performed at least 15 percutaneous nephrostomies as primary operator, with acceptable outcomes, to be considered qualified as a supervising physician (ACR, 2007). Training during residency is the most effective process for developing the skills, but maintenance of skills requires ongoing experience. In a survey of urologists who completed a single residency program, those trained in percutaneous access were more likely to perform percutaneous surgical procedures than those not trained in percutaneous access (92% vs. 33%). Of those who performed percutaneous surgery, urologists with training performed more procedures than those without training (14.0 vs. 3.3 procedures annually). However, only about one third of respondents in both groups continued to attain their own percutaneous access (27% vs. 11%) (Lee et al, 2004a).

Nonhuman models can also assist in training (Laguna et al, 2002). Inanimate trainers can be homemade using gelatin and a vinyl glove (Rock et al, 2010) and Limbs and Things (Savannah, GA) market a commercial model. Several biologic models using ex vivo porcine kidneys incorporate a body wall simulator composed of a chicken carcass (Hammond et al, 2004; Hacker et al, 2007) or full-thickness porcine skin including subcutaneous tissue and muscle, with or without ribs (Strohmaier and Giese, 2009; Imkamp et al, 2011; Qiu et al, 2011). The most advanced trainer is the PERC Mentor (Simbionix, Lod, Israel), a computer-assisted simulator for percutaneous access procedures guided by fluoroscopy (Fig. 8-37).

Figure 8-37. PERC Mentor (Simbionix, Lod, Israel).

Some of the biologic models can be used to teach steps in the subsequent procedure (e.g., nephrolithotomy, endopyelotomy), but the main focus is on attaining percutaneous access. The PERC Mentor has undergone preclinical validation, confirming that training on the PERC Mentor improves performance on the PERC Mentor (Knudsen et al, 2006; Zhang et al, 2013), and that trained individuals more proficiently attain percutaneous renal access in a porcine in vivo model (Margulis et al, 2005), but validation of the impact on performance in the human operating room is lacking (Stern et al, 2007). At the least, these trainers can serve as an introduction for the trainee by orienting them to the necessary anatomic considerations and familiarizing them with the physical movements of the procedure. Whether these or other devices can be used to validate the skills of trainees and practitioners is unknown. Moreover, the most effective training will incorporate cognitive tasks as well as psychomotor ones (Tjiam et al, 2012; Mishra et al, 2013).

Taking simulation even farther, Bruyère and colleagues (2008) used computer-assisted design and rapid prototyping based on CT images to create a silicon model of a patient's kidney, complete with artificial flank and respiratory motion. After practicing percutaneous nephrolithotomy on the model several times, the percutaneous nephrolithotomy on the patient went smoothly using the practiced technique. Creating a specific renal model for each patient is too expensive and laborious for routine application currently, but with anticipated technical improvements, this iteration of "personalized medicine" might play a role in training and treatment planning.

COMPLICATIONS

Given enough time and access sites to the upper urinary tract collecting system, in most cases the primary goal of the percutaneous procedure can be achieved. The challenge with percutaneous surgery, then, is to do so while also avoiding complications. If complications do occur, then prompt recognition and management will usually prevent major morbidity. CT appears to be the most sensitive tool for determining postoperative complications (Semins et al, 2011; Gnassin et al, 2012). Some complications of percutaneous renal surgery are specific to the procedure, including migration of stone outside the kidney, retained foreign bodies such as tips of wires and probes, and tumor seeding of the percutaneous tract. In this section the general complications of percutaneous renal surgery are discussed.

Using the Dindo-modified Clavien system to categorize complications following percutaneous nephrolithotomy, 77% of patients in a systematic review of reports including a total of 11,929 patients experienced no complications (Clavien 0) (Seitz et al, 2012). An additional 11% of patients exhibited only minor deviations from the normal postoperative course (only minimal pharmacologic treatment, Clavien 1), and 7.0% showed Clavien 2 complications (includes additional pharmacologic treatment, blood transfusion, and parenteral nutrition). "Major" complications occurred in <5% of patients (4.1% Clavien 3, requiring surgical, endoscopic, or radiologic intervention; 0.6% Clavien 4, including life-threatening complications; 0.04% Clavien 5, mortality). Similar results were reported in a large multi-institutional study (including 5724 patients), which also used the Dindo-modified Clavien system (Labate et al, 2011). Of the patients, 79% had no complications, 16% had Clavien category 1 or 2 complications, and 4.2% had complications categorized as Clavien category 3 or greater.

Acute Hemorrhage

Acute hemorrhage is the most common significant complication of percutaneous access into the upper urinary tract collecting system. Percutaneous nephrostomy alone results in hemorrhage requiring transfusion in 0.5% to 4% of procedures (Radecka and Magnusson, 2004; Wah et al, 2004; ACR, 2007; Rana et al, 2007). With the addition of percutaneous nephrolithotomy, likely owing to the larger caliber of the percutaneous tract and increased intrarenal manipulation, the incidence of hemorrhage requiring

blood transfusion rises to between 0.8% and 20% (Kukreja et al, 2004; Netto et al, 2005; Preminger et al, 2005; Muslumanoğlu et al, 2006; Duvdevani et al, 2007; Chew et al, 2009; Tomaszewski et al, 2010b; Akman et al, 2011; Labate et al, 2011; Keoghane et al, 2012). This wide variation in transfusion rate, which likely is more variable than the rate of significant hemorrhage, reflects differences in the complexity of the procedure, patient factors, and physician triggers for the use of blood products. In a systematic review of reports including a total of 11,929 patients, a 7% blood transfusion rate was reported (Seitz et al, 2012). Factors associated with hemorrhage during percutaneous renal surgery include patient characteristics, multiple access sites, supracostal access, increasing tract size, tract dilation with methods other than balloon dilation, prolonged operative time, and renal pelvic perforation (Stoller et al, 1994; Martin et al, 1999; Kukreja et al, 2004; Netto et al, 2005; Hegarty and Desai, 2006; Chew et al, 2009; Rastinehad et al, 2009; Akman et al, 2011; Keoghane et al, 2012). In a large multi-institutional study including 5537 patients, the only factors associated with hemorrhage during percutaneous renal surgery were larger sheath size, prolonged operative time, and greater stone burden (Yamaguchi et al, 2011).

Technical errors predispose to hemorrhage as well. Infundibular entry risks injury to interlobar (infundibular) arteries. Access into an anterior calyx or any calyx that does not afford direct access to the pathology invites overly aggressive torquing of the sheath and rigid endoscope, which also can lead to hemorrhage. If direct access cannot be obtained, then flexible instrumentation should be considered. Additionally, misuse of any tool—lithotrites, resectoscopes, wires, sheaths, graspers, baskets, and so on—can cause hemorrhage.

Most hemorrhage occurs from the renal parenchyma, and in most cases this hemorrhage is not significant. Small arteries and veins are always injured to some degree by percutaneous entry into the kidney. Parenchymal bleeding is minimized by proper entry and dilation and by careful manipulation of the sheath, but it still can occur. The access sheath provides intraoperative tamponade of parenchymal bleeding. Postoperatively, hemostasis is achieved by collapse of the parenchyma onto itself. Unless the postoperative nephrostomy tube is as large as or larger than the sheath used during the procedure, it likely does not contribute to hemostasis. There is no difference in measures of postoperative bleeding between small (8- to 18-Fr) and large (20- to 28-Fr) tubes (Maheshwari et al, 2000; Liatsikos et al, 2002; Pietrow et al, 2003; Desai et al, 2004; Marcovich et al, 2004; De Sio et al, 2011), and randomized controlled trials suggest that hemorrhage is no greater when the nephrostomy tube is omitted altogether (Shen et al, 2012). If there is noticeable bleeding from the tract after sheath removal following an otherwise unremarkable procedure, this suggests bleeding from intraparenchymal vessels. Hemostatic maneuvers such as cauterization or placement of hemostatic material can be considered, but in general the best management is to insert and occlude a nephrostomy tube, apply pressure to the incision, and allow the collecting system to clot off. A tubeless approach is not advised in such cases because maintenance of percutaneous access to the upper tract might facilitate management. Nephrostomy tubes should not be irrigated on the day or evening of the procedure if they are not draining; it is best to allow the collecting system to remain occluded to tamponade bleeding. By the next morning, it is safe to irrigate the tube gently because hemostasis is more certain.

If the procedure was not complicated by bleeding, but severe hemorrhage occurs following sheath removal and is refractory to the hemostatic measures described earlier, then use of a Kaye Nephrostomy Tamponade Balloon (Cook Urological, Spencer, IN) should be considered. This is a nephrostomy tube surrounded by a balloon (Fig. 8-38) (Kaye and Clayman, 1986), which is inflated up to 36 Fr to tamponade the parenchymal bleeding just as the sheath did intraoperatively. This device should be removed under fluoroscopic guidance with guidewire access down the ureter in case tube reinsertion is required for recurrent bleeding.

Intraoperative hemorrhage from an injured vein or artery within the collecting system mandates cessation of the procedure

Figure 8-38. Kaye Nephrostomy Tamponade Balloon.

if vision is lost. In most cases, especially if the injury appears to be venous, then placing a nephrostomy tube and letting the collecting system clot off is effective. If this is not effective, however, Gupta and colleagues (1997) have described the insertion of a Councill catheter as a nephrostomy tube, with the balloon inflated slowly at the site where contrast material enters into the venous system until repeated nephrostography shows no more extravasation of contrast material (Fig. 8-39). A hole should be cut into the tube proximal to the balloon to provide drainage of calyces obstructed by the balloon (Fig. 8-40). Millard and associates (2010) have reported an addition to this technique, in which gelatin matrix hemostatic sealant is injected into the tract peripheral to the balloon occluding the renal injury and then a second catheter is inserted with the balloon placed just underneath the skin surface, such that the tract is occluded and the gelatin matrix hemostatic sealant contributes to hemostasis. Another alternative, described in one case of a large venous injury, is to place a large-bore catheter through the injury site into the main renal vein and then back it out several days later (Shaw et al, 2005). A small arterial injury can sometimes be addressed with fulguration under direct vision, but if this is not successful and bleeding does not cease with pressure, or in cases of significant arterial hemorrhage, then selective angioembolization will likely be required (see later).

Delayed Hemorrhage

Postoperative hemorrhage can occur with the nephrostomy tube in place, at time of tube removal, or after discharge from the hospital. Approximately 1% of major percutaneous procedures are complicated by delayed hemorrhage requiring treatment (Kessaris et al, 1995; Martin et al, 2000; Richstone et al, 2008; Tomaszewski et al, 2010b; Keoghane et al, 2012). In one large series, the incidence was greatest following percutaneous resection of upper tract urothelial carcinoma (3.2%) and least following percutaneous endopyelotomy (0.8%) (Richstone et al, 2008). In a systematic review of reports including a total of 11,929 patients, a 0.4% rate of delayed hemorrhage requiring treatment was reported (Seitz et al, 2012). Delayed hemorrhage is usually a result of arteriovenous fistulas or arterial pseudoaneurysms, with the latter being more common. Arteriovenous fistulas occur when a paired set of artery and vein is injured, and arterial blood enters directly into the vein (Fig. 8-41). The weak vein wall cannot sustain the high arterial pressure and ruptures. Bleeding into the collecting system is most commonly noted, but it can be outside the kidney as well. The latter should be suspected if the hematocrit falls but the urine remains relatively clear. It can be confirmed with CT or ultrasonography. An arterial pseudoaneurysm occurs when an artery is injured, clots off, and then intermittently ruptures, often clotting off again at variable intervals (Fig. 8-42A). Continuous bleeding suggests an arteriovenous fistula, and intermittent bleeding suggests arterial pseudoaneurysm, but the distinction is not critical because treatment is the same. In a large series conducted by Kessaris and colleagues (1995), of the 0.8% of 2200 patients requiring treatment for

Figure 8-39. A, Nephrostogram shows contrast material entering the renal vein (RV), indicating a large venous injury. B, The balloon of a Council catheter nephrostomy tube is inflated at the site of injury (C) until contrast material no longer enters the RV.

Figure 8-40. An extra hole created proximal to the balloon of the Council catheter allows for drainage of calyces obstructed by the balloon.

Figure 8-41. Angiography of the renal artery (RA) is followed promptly by contrast material appearing in the inferior vena cava (IVC), suggesting the presence of an arteriovenous fistula (AVF).

delayed hemorrhage after percutaneous renal surgery, 24% of the hemorrhages occurred within 24 hours of surgery, 41% between 2 and 7 days after surgery, and 35% more than 7 days later. Any report of bright red blood in the urine after percutaneous renal surgery should prompt hospital admission and consideration of angiography, which is diagnostic in more than 90% of

cases (Richstone et al, 2008). The standard treatment of renal arteriovenous fistulae and arterial pseudoaneurysms is selective angioembolization, which is highly effective. Among five series reporting a total of 109 patients undergoing selective angioembolization after percutaneous renal surgery, there was success after a single treatment in 98 patients (90%) (Patterson et al, 1985; Martin

Figure 8-42. A, Angiography demonstrates a pseudoaneurysm in the lower pole of the right kidney. B, Angioembolization was successful at occluding the pseudoaneurysm, but it also devascularized a large portion of the lower pole.

Figure 8-43. Covered arterial stent placed in branch of renal artery injured during endopyelotomy. A, Stent before balloon expansion. B, Stent after balloon expansion. Inset in each image is a 2× enlargement of stent (arrows).

et al, 2000; Richstone et al, 2008; Jain et al, 2009; Ji et al, 2012). Nephrectomy may be required if selective angioembolization fails, and partial or total renal loss may occur if angioembolization is not selective enough (Fig. 8-42B). Additionally, the embolization coils can migrate to unwanted locations immediately or this migration might be delayed.

A recently introduced alternative to angioembolization is endovascular placement of a covered stent to occlude the site of arterial injury (Sprouse and Hamilton, 2002; Areste et al, 2005). This treatment maintains patency of the feeding artery, thereby preserving renal parenchyma, and obviates the risk of migration of embolization coils (Fig. 8-43). Another alternative is ultrasonographically guided percutaneous puncture of an arterial pseudoaneurysm, with injection of thrombin or fibrin tissue adhesive into the pseudoaneurysm (Benjaminov and Atri, 2002; Lagana et al, 2006; Sakr et al, 2009).

Untreated coagulopathy is an absolute contraindication to percutaneous renal surgery. Percutaneous access can be obtained safely if coagulopathy is reversed or anticoagulant medications are stopped. Anticoagulants can be restarted after the urine clears, preferably after nephrostomy tube removal, but the patient should be closely monitored.

Collecting System Injury

Tears in the infundibulum are not uncommon during percutaneous surgery of the upper urinary tract collecting system. They generally do not cause problems intraoperatively as long as there is no hemorrhage. Ureteral injuries are rare but can occur as a result of inflating the ureteral balloon occlusion catheter in the ureter or during other ureteral manipulation. These injuries generally will heal over a ureteral stent. Renal pelvic perforation can occur during initial

Figure 8-44. Renal pelvic perforation confirmed with injection of contrast material through flexible nephroscope.

access or during dilation. Pushing too hard on a renal pelvic stone during lithotripsy, or misusing a lithotripter or resectoscope, can also perforate the renal pelvis. Renal pelvic perforation is usually recognized intraoperatively (Fig. 8-44). Collapse of a previously distended renal pelvis is a usual sign if the perforation is not visualized directly at first. A perforation that has not been recognized intraoperatively might be heralded by postoperative abdominal distention, ileus, and/or fever. If noted intraoperatively, abort the procedure unless it is near completion, in which case the task can be completed at lower irrigation pressure if the patient is doing well clinically. At the completion of a case in which renal pelvic perforation has been noted, insert a nephroureteral stent or a nephrostomy tube plus an internal ureteral stent to optimize drainage, and then wait 2 to 7 days before nephrostography and tube removal, depending on the severity of the injury. If renal pelvic perforation is detected postprocedure, despite adequate drainage of the collecting system, then placement of a percutaneous drain into the urinoma might be required. There have been reports of massive intra-abdominal collection of extravasated fluid after percutaneous renal surgery (Peterson et al, 1985; Pugach et al, 1999; Ghai et al, 2003; Etemadian et al, 2012).

Visceral Injury

Any abdominal organ close to the kidney can be injured during percutaneous renal surgery including the colon, duodenum, jejunum, spleen, liver, and biliary system.

Colon injury occurs during percutaneous renal surgery in the prone position at a rate of less than 1% (Segura et al, 1985; Lee et al, 1987; Gerspach et al, 1997; El-Nahas et al, 2006; Duvdevani et al, 2007; Michel et al, 2007; Kachrilas et al, 2012). As one would expect based on the anatomy, with the apposition of the colon to the kidney being greatest on the left side and at the lower pole, the left colon is injured twice as often as the right colon, and the majority of colon injuries involve access to the lower pole (El-Nahas et al, 2006). Additional risk factors include advanced patient age, dilated colon, previous colon surgery or disease, thin body habitus, and the presence of a horseshoe kidney (Goswami et al, 2001; El-Nahas et al, 2006; Michel et al, 2007; Korkes et al, 2009). Injury might be less likely with the patient in the supine position; one study reported a retrorenal colon on CT in 1.9% of

patients in the supine position versus 10% in prone patients (Hopper et al, 1987). The clinical incidence of colon injury, however, is much lower than this figure suggests.

Intraoperative detection of colonic injury confers easier management. If not determined intraoperatively, colon injury should be considered postoperatively if a patient develops unexplained fever, prolonged ileus, unexplained leukocytosis, rectal bleeding, evidence of peritoneal inflammation, or fecaluria or pneumaturia. Clinically apparent nephrocolonic fistula may be the presenting sign, or the injury may not be noted until the time of postoperative nephrostogram. **Most colon injuries are extraperitoneal and can be managed conservatively** (Gerspach et al, 1997; El-Nahas et al, 2006; Korkes et al, 2009; Traxer, 2009; Goger et al, 2012; Kachrilas et al, 2012). The main principle of care is prompt and separate drainage of the colon and urinary collecting system. The surgeon should back out the offending nephrostomy tube into the colon to serve as a colostomy tube, consider exchanging it for a larger tube to enhance colonic drainage, and obtain separate access to the upper urinary tract with either a new percutaneous access that does not traverse the colon or a retrograde-placed ureteral stent. Administer broad-spectrum antibiotics. Give nothing by mouth for a few days, and then start clear liquids. If there is no increase of colostomy output, then administer high-calorie protein supplementation and eventually a regular diet. Parenteral feeding is usually not required. Confirm lack of communication between the colon and collecting system with contrast injection of the tubes before removing them. If the injury is intraperitoneal, or if the patient develops peritonitis or sepsis, then open surgical repair may be required.

Small bowel injuries are even less common than colonic injury, described in only a few case reports (Culkin et al, 1985; Morris et al, 1991; Kumar et al, 1994; Ahmed and Reeve, 1995; Santiago et al, 1998; Lopes-Neto et al, 2000; Al-Assiri et al, 2005; Ricciardi et al, 2007; Traxer, 2009; Winer et al, 2009). Detection is by clinical signs and symptoms of peritonitis or by noting a nephroenteric fistula during postoperative nephrostography. Although open surgery may be required, conservative management using percutaneous intraduodenal catheterization or simple nasogastric or nasoduodenal drainage, combined with drainage of the upper urinary tract, fasting, and parenteral feeding, has been successful.

Studies based on CT and MRI have suggested that splenic and hepatic injuries should be unlikely unless the kidney is accessed above the 10th rib, although access above the 11th or 12th rib might traverse these organs in rare cases (Hopper and Yakes, 1990; Robert et al, 1999). If splenomegaly or hepatomegaly is present, these relationships change and access guided by CT is recommended. Splenic or hepatic injuries to orthotopic and normal-sized organs occur almost exclusively with supracostal upper pole renal access. Splenic injury might require laparotomy and potentially splenectomy owing to hemorrhage (Kondas et al, 1994; Shah et al, 2007), but conservative management has been successful as well (Goldberg et al, 1989; Santiago et al, 1998; Carey et al, 2006; Schaeffer et al, 2008; Thomas et al, 2009; Desai et al, 2010). Liver injury is less likely to be associated with significant hemorrhage—indeed the liver can be traversed percutaneously to obtain biliary access (Nadler et al, 2002), and purposeful transhepatic percutaneous renal surgery has been reported (Matlaga et al, 2006). As such, liver injuries during percutaneous renal surgery can be managed conservatively (El-Nahas et al, 2008).

There have been a few reported cases of biliary peritonitis resulting from injury of the gallbladder or biliary tree, which require exploratory laparotomy/laparoscopy and cholecystectomy owing to the high mortality rate of bile peritonitis (Martin et al, 1996; Saxby, 1996; Kontothanassis and Bissas, 1997; Fisher et al, 2004; Ricciardi et al, 2007; Patel and Nakada, 2010). Postoperative pancreatitis, without evidence of direct pancreatic injury, has been described as well (Chitale et al, 2005).

Pleural Injury

Hydrothorax, and occasionally pneumothorax, is a risk of percutaneous access to the upper urinary tract collecting system.

Supracostal access is the main risk factor; access below the 12th rib rarely results in hydrothorax or pneumothorax (<0.5%) (Munver et al, 2001; Radecka et al, 2003; Lojanapiwat and Prasopsuk, 2006; Maheshwari et al, 2009). The incidence of pleural complications with punctures above the 12th rib (the 11th intercostal space) is generally considered an acceptable risk if that approach provides optimal access to the upper urinary tract. Access above the 11th rib or higher carries a much greater risk of pleural injury. Among 16 reports that distinguished between access above the 12th rib and access above the 11th rib, reporting a total of 1384 supracostal percutaneous accesses, the incidence of hydro/pneumothorax that required intervention varied from 0% to 18% for access superior to the 12th rib (weighted mean of 4.6%) and from 0% to 100% for access superior to the 11th rib (weighted mean of 24.6%) (Young et al, 1985; Picus et al, 1986; Narasimham et al, 1991; Golijanin et al, 1998; Kekre et al, 2001; Munver et al, 2001; Gupta et al, 2002; Wong and Leveille, 2002; Muzrakchi et al, 2003; Radecka et al, 2003; Aron et al, 2005; Lojanapiwat and Prasopsuk, 2006; Yadav et al, 2006; Shaban et al, 2008; Sukumar et al, 2008; Yadav et al, 2008).

Nephropleural fistula (urinothorax) is a direct and persistent communication between the intrarenal collecting system and the intrathoracic cavity (Ray et al, 2003; Shleyfer et al, 2006; Handa et al, 2007). It can follow percutaneous renal access of the upper urinary tract in the setting of pleural transgression. Some degree of distal ureteral obstruction usually contributes to the problem. Most commonly, nephropleural fistula is diagnosed after the percutaneous tube is removed, but it can occur in the setting of a recognized hydrothorax when the persistent communication is documented on nephrostography at the time of intended tube removal. Lallas and colleagues (2004) reported that nephropleural fistula never occurred in association with subcostal access but did complicate 2.3% of punctures superior to the 12th rib and 6.3% of punctures superior to the 11th rib.

Pleural complications of supracostal percutaneous access can often be detected with chest fluoroscopy during or at the conclusion of the procedure. Fluid can be seen tracking along the lateral borders of the chest cavity and compressing the ipsilateral lung. Although postoperative chest radiography is more sensitive than intraoperative fluoroscopy, some authors report that thoracostomy was never required on the basis of postoperative chest radiography when intraoperative chest fluoroscopy was negative (Ogan et al, 2003; Bjurlin et al, 2012). Nonetheless, formal chest radiography is recommended following all cases of supracostal percutaneous renal access.

Thoracostomy is not necessary for all patients with hydrothorax. If hydrothorax is noted intraoperatively, then insert a small-caliber (8-Fr to 12-Fr) Cope nephrostomy tube as the thoracostomy (Fig. 8-45), using fluoroscopic guidance and the same general techniques as for antegrade percutaneous renal access (Ogan and Pearle, 2002). A Heimlich valve, rather than water seal drainage, is all that is necessary in the absence of lung injury. If a hydrothorax is noted on the postoperative chest radiograph, then place a small-caliber tube only if the effusion is large or if there is evidence of respiratory compromise or hemodynamic instability. A large-bore thoracostomy tube for lung injury is rarely required.

Metabolic and Physiologic Complications

Normal saline should be the irrigant for percutaneous renal surgery, with the exception of glycine or similar nonelectrolytic isotonic fluids when monopolar electrocautery is used. Irrigation with water during percutaneous renal surgery risks intravascular hemolysis, which can be fatal. At least one death associated with water irrigation during percutaneous nephrolithotomy has been described (Bennett et al, 1984), and the author is aware of an unreported case. Intravascular or extravascular extravasation of nonelectrolytic isotonic fluid from continued irrigation in the setting of a large venous injury or collecting system perforation, respectively, can result in hyponatremia and other electrolyte abnormalities, renal or hepatic dysfunction, and mental status changes. When

Figure 8-45. A 12-Fr Cope catheter placed into the chest when a large hydrothorax was noted intraoperatively on fluoroscopy.

normal saline is used in uncomplicated cases, the amount of fluid absorption is generally clinically insignificant (Kukreja et al, 2002; Koroglu et al, 2003), although in one study 28% of patients absorbed more than a liter (Malhotra et al, 2001). A large amount of saline extravasation can lead to clinically significant respiratory distress or cardiac failure resulting from volume overload.

Venous gas embolism is a rare but potentially fatal complication of percutaneous renal surgery. The gas (in this case, air) enters the venous system and passes through the right heart into the pulmonary circulation, blocking the output of the right heart, which results in hypoxemia, hypercapnia, and depressed cardiac output. Gas can also pass through a patent foramen ovale to enter the arterial system, which can result in neurologic deficits. Among six reported cases of venous gas embolism in association with percutaneous renal surgery, three were associated with air pyelography in combination with percutaneous access of the kidney (Miller et al, 1984; Cadeddu et al, 1997a; Droghetti et al, 2002), one involved percutaneous surgery without air pyelography (Turillaz et al, 2009), and two occurred after retrograde injection of air into the renal pelvis but before percutaneous puncture (Varkarakis et al, 2003; Song et al, 2007). Venous gas embolism is indicated by hypoxemia, evidence of pulmonary edema, increased airway pressure, hypotension, jugular venous distention, facial plethora, dysrhythmias, and auscultation of a mill-wheel cardiac murmur and/or the appearance of a widened QRS complex with right heart strain patterns on electrocardiography. The most sensitive measure is a sudden decrease in capnometry reading of the P(end-tidal)CO₂. Swift response is required and includes rapid ventilation with 100% oxygen, positioning the patient head down with the right side up, and general resuscitative maneuvers.

Postoperative Fever and Sepsis

After percutaneous nephrolithotomy, 15% to 30% of patients develop a fever. Risk factors for fever/infectious complications following percutaneous nephrolithotomy include diabetes mellitus, paraplegia, indwelling ureteral stent or nephrostomy tube, previous percutaneous nephrolithotomy, multiple access tracts, infection stone, positive preoperative urine culture, larger stones, and hydro-nephrosis (Charton et al, 1986; Troxel and Low, 2002; Aghdas et al,

2006; Draga et al, 2009; Korets et al, 2011; Lojanapiwat and Kitirattrakarn, 2011; Kumar et al, 2012; Gutierrez et al, 2013). Most patients with fever after percutaneous nephrolithotomy, assuming appropriate antimicrobial prophylaxis, do not have infection (Cadeddu et al, 1998). Sepsis occurs in 0.5% to 2.5% of patients after percutaneous nephrolithotomy (Dogan et al, 2007; Duvdevani et al, 2007; Gonen et al, 2008b; Labate et al, 2011; Lojanapiwat and Kitirattrakarn, 2011; Seitz et al, 2012; Li et al, 2013a). Sepsis implies an infection, which is not always present; “systemic inflammatory response syndrome” is a more accurate description. Positive preoperative urine cultures should be treated. Even if bacteriologic cure is not possible (e.g., infectious stone, indwelling nephrostomy tube), bacterial counts should be suppressed as much as possible to reduce the risk of infectious complications. Nonetheless, a negative urine culture does not guarantee against sepsis because the voided urine culture may not reflect the intrarenal urine (Rao et al, 1991; Mariappan et al, 2005; Lojanapiwat and Kitirattrakarn, 2011; Korets et al, 2011). Because the febrile patient who will progress to sepsis cannot be predicted, careful observation, appropriate diagnostic evaluation, and initiation of antimicrobial therapy and other supportive care are indicated if a postoperative fever does not resolve promptly.

If pus is aspirated upon initial percutaneous entry to the upper urinary tract, the safest measure is to abort the procedure and leave a nephrostomy tube for drainage. Aron and associates (2005a), based on their experience in 19 patients with purulent fluid from the kidney at initial puncture for percutaneous nephrolithotomy, suggested that aborting the procedure might not always be necessary. They continued the procedure in 12 patients and delayed it in 7. Of the 12 patients in whom the procedure was continued, two (17%) experienced postprocedure sepsis. Among the seven patients in whom the procedure was delayed (for 3 to 7 days), two (29%) developed sepsis after the second procedure (both of whom had additional portions of the kidney containing undrained pus, which were discovered at the time of the delayed percutaneous nephrolithotomy). An important difference was in the quality of the aspirated material. One patient in whom percutaneous nephrolithotomy was continued and two in whom the procedure was delayed had “frank pus” as opposed to “purulent fluid” in the other cases. All three of these patients with frank pus were among the four who developed sepsis. The authors recommend that if frank pus is aspirated, then the procedure should be aborted. If the aspirate is a cloudy nonviscous liquid, it might be safe to proceed. This approach has not yet been validated in additional studies. This report also suggests that not all patients with “purulent fluid” are infected. Of the 19 patients, the culture of the aspirate showed bacteria in only 6. This suggests that infection may have been sterilized by previous antibiotic use. The turbid fluid may indicate a sterile inflammatory response to the stone, or the fluid may consist of debris related to the renal calculus. Another important point is that a single nephrostomy tube may not drain all areas of infection in the kidney, especially if there is intrarenal obstruction.

Neuromusculoskeletal Complications

Prone positioning for percutaneous renal surgery has the potential for a number of neuromusculoskeletal injuries (Shermak et al, 2006; Edgcombe et al, 2008). Excessive pressure on neural and vascular structures, whether directly from the operative table or indirectly through the positioning of limbs, may lead to short- or long-term disability. Most reported injuries associated with prone positioning are related to the head and neck region including ocular injury resulting in visual loss, facial nerve injury or necrosis over facial bones or the tip of the nose, and cerebrovascular accident resulting from carotid or vertebralbasilar artery dissection. Careful padding of the head, in a neutral and nonextended position, is important. Malpositioning of the extremities can lead to peripheral nerve injury (Winfree and Kline, 2005). The shoulder and elbow should not be abducted more than 90 degrees, so as to prevent brachial plexopathy, and generous padding at the elbow and forearm reduces the risk of nerve compression. Knees need to be

padded. Ankles should be elevated to reduce pressure on the dorsum of the foot.

Venous Thromboembolism

The incidence of venous thromboembolism with percutaneous renal surgery is low (<3% in older series of percutaneous nephrolithotomy) (Segura et al, 1985; Lee et al, 1987), but there are no recent data. The AUA's Best Practice Statement for the prevention of deep vein thrombosis in patients undergoing urologic surgery does not include percutaneous renal surgery among procedures for which prophylaxis against venous thromboembolism is recommended (Forrest et al, 2009). Early ambulation is the best measure to reduce the already low risk of venous thromboembolism.

Tube Dislodgement

Whether the percutaneous nephrostomy tube is intended to be short term or long term, inadvertent tube dislodgement risks poor patient outcomes. The tube does not need to fall out of the patient completely; especially in a patient with a large subcutaneous layer, the tube can remain attached at the skin but pull out from within the kidney when the distance between the skin and kidney increases with patient movement. Nonetheless, all tubes should be secured at the skin to reduce the risk of at least one mechanism of tube removal. Tubes vary in their inherent ability to resist removal. Malecot tubes are the easiest to pull out, and circle nephrostomy tubes are the most difficult. The Cope retention mechanism is more secure than Malecot wings but does not retain as well as a balloon (Canales et al, 2005). For long-term indwelling, circle nephrostomy tubes and Cope nephrostomy tubes are most commonly used. Ironically, the Malecot tube is also the one most likely to become entrapped; tissue can grow over the wings, making removal difficult and traumatic (Sardina et al, 1995; Tasca and Cacciola, 2004).

If a nephrostomy tube has been in for only a short time, then complete dislodgement often leads to complete loss of percutaneous access. Using a nephrostomy tube with a ureteral extension, whether it is only partially down the ureter as in the Malecot re-entry tube or all the way into the bladder as in a nephroureteral stent, will increase the chance of having some access back into the kidney even if the renal retention device pulls out of the kidney. For tubes that have been in place for more than a few weeks, the tract is usually mature enough that carefully probing with an angled hydrophilic wire and judicious use of contrast material to outline the tract can allow restoration of the percutaneous access. Tube malposition can usually be corrected under fluoroscopic control, but guidance by CT might be helpful as well (Jones and McGahan, 1999).

Collecting System Obstruction

Transient ureteral obstruction owing to ureteral edema or blood clot occurs commonly. To assess for this, nephrostomy tubes should be removed after nephrostography or after a period of clamping to assess clinically for distal ureteral obstruction. Much more uncommon is stricture formation, which can occur in the ureter, at the ureteropelvic junction, or in an infundibulum. If the stricture occurs early in the postprocedure course, then a nephrocuteaneous fistula will develop. If it develops late, then hydronephrosis or hydrocalyx will occur. In one large series there was a 2% rate of infundibular stenosis after percutaneous nephrolithotomy (Parsons et al, 2002). The obstructions developed in the areas that had been accessed percutaneously. Predisposing factors in this and other smaller reports (Ballanger et al, 1987; Weir and Honey, 1999; Buchholz, 2001) include large stone burden requiring multiple or long procedures and prolonged nephrostomy tube drainage, previous open stone surgery, diabetes mellitus, and obesity. The ureter (Culkin et al, 1987; Lopes-Neto et al, 2008) and the ureteropelvic junction (Green et al, 1987; Ben Slama et al, 2005) are smaller in

caliber than the intrarenal collecting system and are therefore also susceptible to trauma.

Obstruction after percutaneous renal surgery should respond to endoscopic treatment in most cases, but open surgical reconstruction or excision with partial nephrectomy or total nephrectomy might be required.

Loss of Renal Function

Despite the direct puncture of renal parenchyma and enlargement of sometimes multiple tracts to as much as 34 Fr, the kidney suffers little permanent damage after uncomplicated percutaneous renal surgery. Renal function does decrease slightly immediately after percutaneous renal surgery, reaching a nadir 48 hours postprocedure (Nouralizadeh et al, 2011), but there is negligible long-term loss of function (Ekelund et al, 1986; Chen et al, 1992; Saxby, 1997; Kilic et al, 2006), and in one study there appeared to be less damage to the kidney after percutaneous nephrolithotomy than after shock wave lithotripsy (LeChevallier et al, 1993). In the setting of impaired function, especially because of obstructing calculi, percutaneous surgery will often improve renal function (Chandhoke et al, 1992; Chatham et al, 2002; Bilen et al, 2008). Percutaneous renal surgery also causes no significant change in function of solitary kidneys (Jones et al, 1991; Liou and Streem,

2001; Canes et al, 2009). In one study of patients who were surveyed a mean of 19 years after treatment, there was no difference between shock wave lithotripsy and percutaneous nephrolithotomy in the development of renal insufficiency or hypertension (Krambeck et al, 2008a).

When there is renal loss following percutaneous renal surgery, it usually is a result of disastrous vascular injury or the angioembolization used to treat hemorrhage. In the original AUA guideline on staghorn calculi (Segura et al, 1994), renal loss after percutaneous nephrolithotomy was estimated at 1.6%; data were insufficient to calculate a new figure in the 2005 update of the guidelines (Preminger et al, 2005).

Death

Death after percutaneous renal surgery is extremely rare, and when it occurs it is usually a result of underlying cardiovascular conditions (Labate et al, 2011; Seitz et al, 2012). In the current AUA guideline on the management of staghorn calculi, the median death estimate for percutaneous nephrolithotomy was zero, which reflects the paucity of data on the subject (Preminger et al, 2005).

KEY POINTS: COMPLICATIONS

- Hemorrhage during percutaneous surgery is associated with inappropriate access site, multiple access sites, supracostal access, increasing tract size, tract dilation with methods other than balloon dilation, prolonged operative time, and renal pelvic perforation or other intraoperative technical errors.
- In most cases of hemorrhage during percutaneous surgery or at the time of sheath removal, placing a nephrostomy tube and letting the collecting system clot off is effective. If bleeding is more severe, additional measures may be required.
- Delayed hemorrhage is usually caused by arteriovenous fistulas or arterial pseudoaneurysms. Bright red blood in the urine after percutaneous renal surgery should prompt hospital admission and the consideration of angiography. Selective angioembolization is highly successful in treating this condition.
- If renal pelvic perforation is noted intraoperatively, abort the procedure unless it is near completion. Insert a nephroureteral stent or a nephrostomy tube plus a ureteral stent to optimize drainage.
- Most colon injuries from percutaneous renal surgery are extraperitoneal and can be managed conservatively by draining the colon and urinary collecting system separately.
- Hydrothorax or pneumothorax requiring intervention is related to the level of percutaneous access. Incidence estimates are less than 0.5% below the 12th rib, 4.6% above the 12th rib, and 24.6% above the 11th rib. Pleural complications can often be detected with chest fluoroscopy during the procedure, but a chest radiograph should also be obtained following all cases of supracostal percutaneous renal access.
- Normal saline should be the fluid used for irrigation during percutaneous renal surgery, with the exception of glycine or a similar nonconductive solution when monopolar electrocautery is used.
- If pus is aspirated on initial percutaneous entry to the upper urinary tract, the safest measure is to abort the procedure and leave a nephrostomy tube for drainage.

Classification and Timing of Hematuria

Microscopic Hematuria

Evaluation of Patients with Microhematuria

Symptomatic Microscopic Hematuria

Gross Hematuria

Hemorrhagic Cystitis

Hematuria from Prostatic Origin

Urethral Bleeding

Hematuria Originating from the Upper Urinary Tract

Hematuria has been recognized as a sign of medical illness since antiquity (Ellis, 1979; Shokeir and Hussein, 1999; Armstrong, 2006). Yet it is only in the modern era that we have developed the technology to detect microscopic blood, the means to identify the source of hematuria, and the understanding of anatomy, physiology, and disease processes underlying this important sign. Today, hematuria is one of the most common indications for urologic evaluation (Mariani et al, 1989) and is recognized as a sign of potentially important illness. Therefore knowledge of the differential diagnosis, principles of evaluation, and strategies for management of hematuria is critical.

CLASSIFICATION AND TIMING OF HEMATURIA

Hematuria may be classified according to its visibility and timing during the urinary stream. That is, gross hematuria (GH), sometimes referred to as *frank hematuria*, *macrohematuria*, or *visible hematuria*, is hematuria that can be seen with the naked eye. GH may be further characterized as initial, terminal, or total, depending on the phase of the urinary stream in which it is visible. This characterization may give some indication of the source of hematuria, with initial hematuria most commonly emanating from a urethral source; terminal hematuria from the bladder trigone, bladder neck, or prostate; and total hematuria from the bladder or above (Sokolosky, 2001).

GH must be distinguished from pigmenturia, which may be due to endogenous sources (e.g., bilirubin, myoglobin, porphyrins), foods ingested (e.g., beets and rhubarb), drugs (e.g., phenazopyridine), and simple dehydration. This distinction can be made easily by urinalysis with microscopy. Notably, myoglobinuria and other factors can cause false-positive chemical tests for hemoglobin, so urine microscopy is required to confirm the diagnosis of hematuria. GH also must be distinguished from vaginal bleeding in women, which usually can be achieved by obtaining a careful menstrual history, collecting the specimen when the patient is not having menstrual or gynecologic bleeding, or, if necessary, obtaining a catheterized specimen. GH may also be detected by the presence of blood spotting on the undergarments of incontinent patients. After ruling out vaginal bleeding and mimics of hematuria, a urologic source must be suspected.

MICROSCOPIC HEMATURIA

In contrast to GH, microscopic hematuria, or microhematuria (MH), is a sign rather than a symptom; a laboratory diagnosis defined as the presence of red blood cells (RBCs) on microscopic

examination of the urine not evident on visual inspection of the urine. The prevalence of MH among healthy participants in screening studies is 6.5% (95% confidence interval [CI] 3.4 to 12.2), with higher rates in studies with a predominance of males, older patients, and smokers (Davis et al, 2012). MH may be categorized by the presence or absence of associated symptoms and may be quantified according to number of RBCs per high-power field (HPF). The proper collection of a urine specimen and the details of urine dipstick testing and urinalysis are covered in Chapter 1.

Criteria for the Diagnosis of Microhematuria

A small number of RBCs may pass into the urine even under normal conditions, and normal processes (e.g., sexual activity, exercise) can result in minor amounts of MH (Kohanpour et al, 2012). The American Urologic Association (AUA) guideline panel defined MH as three or more RBCs/HPF, concluding that higher thresholds would lead to missed opportunities to diagnose treatable urologic conditions (Davis et al, 2012). Additionally, it has been shown that MH caused by significant medical conditions, such as urinary tract malignancy, can be intermittent (Davis et al, 2012). In fact, a meta-analysis reported that the rate of malignancy detected among patients evaluated for a single positive urinalysis was 3.6% (Davis et al, 2012). Thus the most recent AUA guideline panel has determined that a single positive urinalysis is sufficient to prompt evaluation (Davis et al, 2012).

Requirement for Microscopic Evaluation

The results of urine dipstick tests must be confirmed on urinalysis with microscopy and alone are considered insufficient to prompt an evaluation. Indeed, chemical tests for hematuria detect the peroxidase activity of hemoglobin using benzidine, and therefore conditions such as myoglobinuria can falsely activate the test (Mariani et al, 1984). Thus a positive dipstick test merits microscopic examination of the urinary sediment, but does not warrant full evaluation unless microscopy confirms the presence of three or more RBCs/HPF. If the urinalysis with microscopy is not confirmatory, but the clinician remains suspicious, repeat microscopic testing is reasonable with the frequency individualized based on provider judgment.

Specimens collected immediately after prolonged recumbency (first void in morning) or after vigorous physical or sexual activity may be falsely positive for hematuria (Addis, 1926; Kincaid-Smith, 1982). Additionally, dilute urine (osmolality <308 mOsm) may result in false-negative microscopic examination as a result of RBC lysis (Vaughan and Wyker, 1971).

Evaluation of Patients with Microhematuria

In most studies, one third to two thirds of patients evaluated for MH have been found to have a demonstrable cause (Mohr et al, 1986; Murakami et al, 1990), including calculus (6.0%), benign prostatic enlargement (12.9%), urethral stricture (1.4%), and various other conditions (Table 9-1) (Davis et al, 2012). Notably, the evaluation of patients with MH yields a diagnosis of malignancy in 1.8% to 4.3% of cases, depending on the characteristics of the population evaluated, the threshold for evaluation, and the completeness of the evaluation (Davis et al, 2012). The likelihood of

identifying a malignancy is higher among patients with higher levels of microscopic hematuria (>25 RBCs/HPH), GH, or risk factors for malignancy (Sultana et al, 1996; Shephard et al, 2012; Loo et al, 2013). Risk factors for malignancy among patients with hematuria include male gender, older age, and tobacco use (Box 9-1).

Selecting Patients for Evaluation of Microhematuria

Recognizing that one third to two thirds of patients with MH will have a negative hematuria evaluation, interest is growing in an evidence-based selection of patients for hematuria evaluation to

TABLE 9-1 Differential Diagnosis of Asymptomatic Microhematuria*

CATEGORY	EXAMPLES	COMMON CLINICAL PRESENTATION AND RISK FACTORS
Neoplasm	Any Bladder cancer Ureteral or renal pelvis cancer Renal cortical tumor Prostate cancer Urethral cancer	See Box 9-1 Older age, male predominance, tobacco, occupational exposures, irritative voiding symptoms Family history of early colon cancers or upper tract tumors, flank pain Family history of early kidney tumors, flank pain, flank mass Older age, family history, African-American Obstructive symptoms, pain, bloody discharge
Infection/inflammation	Any Cystitis Pyelonephritis Urethritis Tuberculosis Schistosomiasis Hemorrhagic cystitis	History of infection Female predominance, dysuria Fever, flank pain, diabetes, female predominance Exposure to sexually transmitted infections, urethral discharge, dysuria Travel to endemic areas Travel to endemic areas See Box 9-2
Calculus	Any Nephroureterolithiasis Bladder stones	Flank pain, family history, prior stone Bladder outlet obstruction
Benign prostatic enlargement		Male, older age, obstructive symptoms
Medical renal disease†	Any Nephritis IgA nephropathy	Hypertension, azotemia, dysmorphic erythrocytes, cellular casts, proteinuria
Congenital or acquired anatomic abnormality	Polycystic kidney disease Ureteropelvic junction obstruction Ureteral stricture Urethral diverticulum Fistula	Family history of renal cystic disease History of UTI, stone, flank pain History of surgery or radiation, flank pain, hydronephrosis; stranguria, spraying urine Discharge, dribbling, dyspareunia, history of UTI, female predominance Pneumaturia, fecaluria, abdominal pain, recurrent UTI, history of diverticulitis or colon cancer
Other	Exercise-induced hematuria‡ Endometriosis Hematologic or thrombotic disease Papillary necrosis Arteriovenous malformation Renal vein thrombosis Interstitial cystitis Trauma Recent genitourinary surgery or instrumentation	Recent vigorous exercise Cyclic hematuria in a menstruating woman Family history of personal history of bleeding or thrombosis African-American, sickle cell disease, diabetes, analgesic abuse Voiding symptoms History History

*Differential diagnosis, having ruled out obvious benign causes, such as menstruation, recent instrumentation, uncomplicated cystitis, etc.

†Presence of hematologic illness, medical renal illness or use of anticoagulants or antiplatelet agents does not preclude the need for a hematuria evaluation.

‡Exercise-induced hematuria is a diagnosis of exclusion. Absence of hematuria after abstinence from exercise must be confirmed.

IgA, immunoglobulin A; UTI, urinary tract infection.

BOX 9-1 Common Risk Factors for Urinary Tract Malignancy in Patients with Microscopic Hematuria

Male gender
 Age older than 35 years
 Past or current smoking history
 Occupational or other exposure to chemicals or dyes (benzenes or aromatic amines)
 Analgesic abuse
 History of gross hematuria
 History of urologic disorder or disease
 History of irritative voiding symptoms
 History of pelvic irradiation
 History of chronic urinary tract infection
 Exposure to known carcinogenic agents or chemotherapy such as alkylating agents
 History of chronic indwelling foreign body

Modified from American Urological Association guidelines.

minimize the financial burden and risks in evaluating all patients (Mohr et al, 1986; van der Molen and Hovius, 2012; Loo et al, 2013). For example, the Kaiser Permanente group demonstrated that, among patients undergoing a complete evaluation for hematuria, those at high risk for malignancy (age >50 years, history of GH, tobacco use, male gender, or >25 RBCs/HPF) had higher rates of malignancy (10.7% to 11.6%) than patients at intermediate (1.1% to 2.5%) or low (0 to 0.3%) risk (Loo et al, 2013). However, although the Kaiser study shows that we may be able to decide which patients referred to urologists can safely avoid complete evaluation, the reality is that fewer than 25% of patients found to have hematuria are referred for evaluation and fewer than 10% undergo a complete evaluation with cystoscopy and imaging, even among patients at high risk for malignancy (Elias et al, 2010; Buteau et al, 2012). Taken together, these studies suggest that ample room exists for improvement in developing evidence-based algorithms to guide the use of hematuria evaluation and in reducing nonclinical sources of variability in adherence to evidence-based practices.

The AUA guidelines recommend evaluating patients with MH “in the absence of an obvious benign cause” such as infection and menstruation. Therefore it is imperative that patients who are found to have MH in the setting of a suspected benign cause have that benign cause substantiated by clinical evidence and be further evaluated once the suspected benign cause is resolved. Unfortunately, uniform agreement does not exist on how to identify benign causes of hematuria. Perhaps, as a result, substantial delays in diagnosis and inferior bladder cancer outcomes have occurred related to repeated empirical treatment of urinary tract infection (UTI) and voiding symptoms, particularly among women (Henning et al, 2013; Lyratzopoulos et al, 2013; Tracey et al, 2014). Our recommendation is that the presence of infection should be confirmed with a urine culture and the urinalysis should be repeated after treatment of the UTI to document resolution of the hematuria. If hematuria persists, further evaluation is warranted.

In addition, recent vigorous exercise may be associated with MH, but this entity should be considered a diagnosis of exclusion (Kincaid-Smith, 1982; McInnis et al, 1998; Kohanpour et al, 2012). Thus it is necessary to confirm the absence of MH after a period of abstinence from exercise. In addition, patients who develop hematuria (microscopic or gross) who are taking anticoagulation or antiplatelet medications (e.g., warfarin, enoxaparin, heparin, aspirin, clopidogrel, nonsteroidal anti-inflammatory agents) should undergo a complete evaluation in the same manner as patients not taking such medications, because the prevalence of hematuria, as well as the likelihood of finding genitourinary

cancers, among patients with hematuria on anticoagulation has been reported to be no different from patients not taking such medications (Culclasure et al, 1994; Khadra et al, 2000; Davis et al, 2012; Jeong et al, 2013). In fact, it has been noted that these medications may unmask genitourinary lesions at an earlier stage (Antolak and Mellinger, 1969; Kraus et al, 1984; Schuster and Lewis, 1987; Mariani, 1989). In one series, 82% of anticoagulated male patients evaluated for GH were found to have significant urologic lesions (Antolak and Mellinger, 1969), and 13.9% of such lesions in another series were found to be malignant (Schuster and Lewis, 1987). Meanwhile, MH in the setting of trauma is detailed elsewhere (see Chapters 50 and 101) and will not be covered here.

The Question of Screening for Hematuria and Bladder Cancer

Bladder cancer is the sixth most commonly diagnosed cancer in the United States, and although no large-scale screening trials have been performed, most believe that the harms and costs of mass screening for bladder cancer would prove to outweigh the potential benefits (<http://seer.cancer.gov/statfacts/html/urinb.html>; Chou and Dana, 2010). Nonetheless, many primary care providers perform urinalysis as part of routine health examinations, creating numerous opportunistic screening events (Prochazka et al, 2005).

KEY POINTS: MICROSCOPIC HEMATURIA

- MH is defined as three or more RBCs/HPF, identified on one or more occasions on urine microscopy. Urine dipstick testing is insufficient for the diagnosis of MH.
- MH is quite common, with a prevalence of approximately 6.5% of adults, varying according to the characteristics of the population.
- Malignancy has been detected in approximately 4% of patients evaluated for asymptomatic MH. The proportion of malignancies detected is higher in patients with higher degrees of hematuria and/or risk factors for malignancy.

EVALUATION OF PATIENTS WITH MICROHEMATURIA

See Figure 9-1 for the evaluation algorithm of MH from the most recent AUA guidelines (Davis et al, 2012). Importantly, it is recommended that patients meeting criteria for evaluation undergo a complete evaluation, even if one phase of the evaluation shows a suspected cause for the MH. For example, a patient found to have a kidney tumor or stone disease during initial workup of MH should still undergo cystoscopy for clearance of bladder and urethral pathologic processes.

The evaluation of an appropriately selected patient with MH begins with a thorough history and physical examination. Specifically, one should aim to identify causes that would warrant variation from the standard evaluation, such as infection, menstruation, recent vigorous exercise, known medical renal disease, acute viral illness, trauma, and the presence of foreign bodies in the urinary tract or recent urologic instrumentation. The history also should include an assessment of associated symptoms, such as GH, voiding symptoms, or flank pain. Patients' risk factors for known causes of hematuria also should be queried. It is important to know the patient's urologic history, particularly any surgeries or febrile UTIs. It is also critical to ask about the patient's general medical history, to identify potentially contributory diagnoses, such as hypertension, renal insufficiency, bleeding disorders, or sickle cell disease. Current medication use, including anticoagulants and antiplatelet therapies, should be elicited, along with recent coagulation values and any concomitant medications that would potentiate the effects of blood thinners. Family history of nephritis, polycystic kidneys, and rare familial tumor syndromes of the kidney (e.g., von Hippel-Lindau) or urothelium (e.g., Lynch syndrome) also may

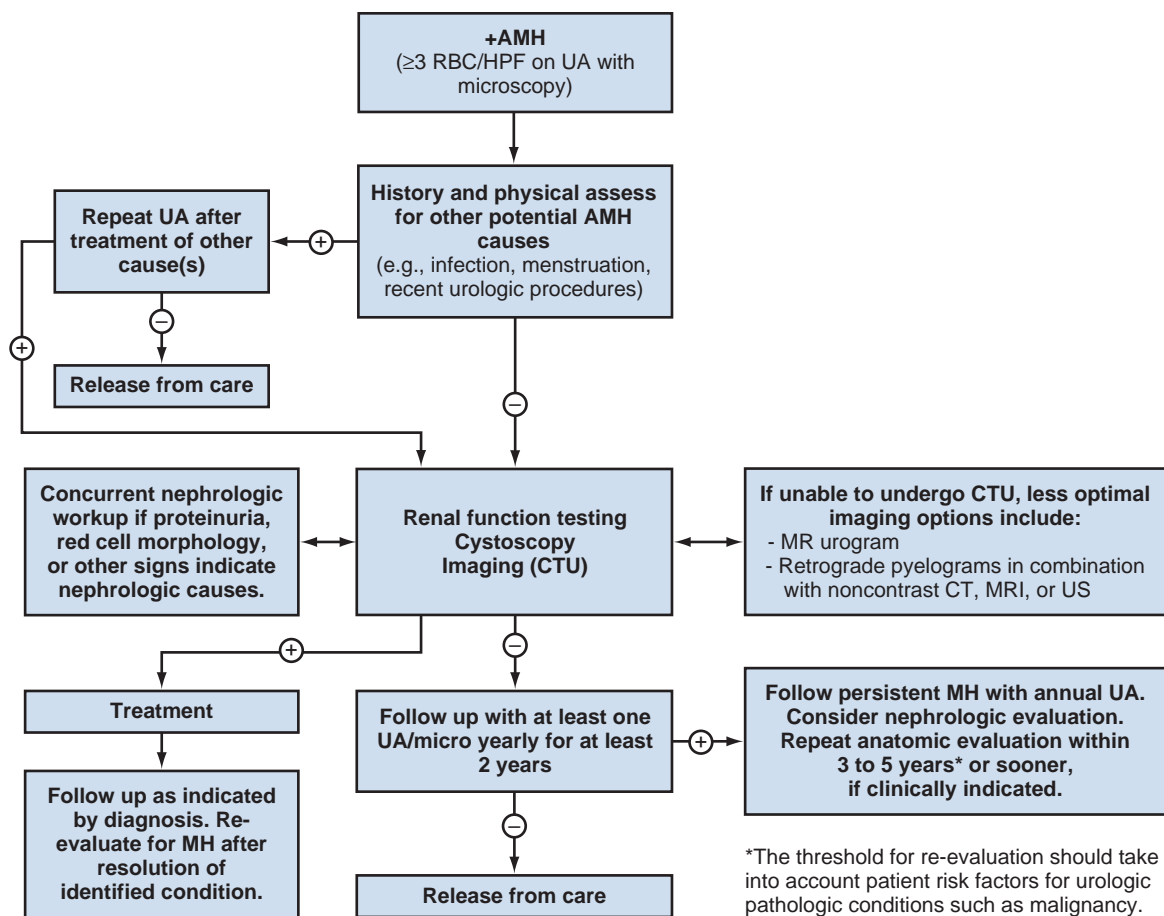

Figure 9-1. American Urological Association guideline algorithm for evaluation of adult patients with asymptomatic microhematuria. AMH, asymptomatic microhematuria; CT, computed tomography; CTU, computed tomography urogram; HPF, high-power field; MH, microhematuria; MR, magnetic resonance; MRI, magnetic resonance imaging; RBC, red blood cell; UA, urinalysis; US, ultrasound. (From the American Urological Association.)

be informative. In addition, the possibility of finding a tobacco-related illness, such as bladder cancer, makes this a potential “teachable moment” for tobacco users (Bassett et al, 2012; Fiore and Baker, 2013). Thus smoking cessation counseling should be a standard component of the hematuria evaluation discussion.

Physical examination should focus on the genitourinary system (e.g., flank tenderness; masses in the flank, abdomen, suprapubic area, or urethra; and enlarged, nodular, tender, or fluctuant prostate.) Physical examination also may identify signs of coagulopathy (bruising), infection (fever), or renal disease (hypertension, edema). If urethral stricture or benign prostatic hyperplasia (BPH) is suspected, a urine flow rate and postvoid residual measurement may be helpful as well.

Laboratory testing includes urinalysis (if not performed previously) to confirm the presence of hematuria and check for dysmorphic red cells, cellular casts, or proteinuria; a urine culture if the urinalysis or clinical presentation suggests infection; renal function testing (serum creatinine) to determine whether concomitant nephrologic evaluation is indicated and to guide the selection of appropriate upper tract imaging; and prostate-specific antigen in the appropriate setting.

If a benign cause of hematuria is discovered during the initial history and physical (e.g., UTI), that cause should be verified and treated and then the urine should be retested to ensure that the hematuria has resolved in the absence of the presumed benign cause. Moreover, if a medical renal cause of hematuria is suspected based on the presence of renal insufficiency, hypertension, or abnormalities on urinalysis, nephrology evaluation is

recommended, but the patient should still undergo urologic evaluation.

Cystoscopy in the Diagnostic Evaluation of Hematuria

Cystoscopy is a key component of the hematuria evaluation because it is the most reliable way to evaluate the bladder for the presence of bladder cancer and provides the opportunity to evaluate the urethra. Cystoscopy should be performed in all adults who meet criteria for hematuria evaluation who are 35 years of age or older and/or have risk factors for malignancy. The potential risks include discomfort, injury to the urethra, infection, and the need for additional procedures, such as biopsy. At the population level, bladder cancer is quite rare (<1 per 100,000) among persons 35 years old or younger (van der Molen and Hovius, 2012; <http://seer.cancer.gov/statfacts/html/urinb.html>). That is, among 3762 individuals with asymptomatic MH from 17 screening studies, 98 (2.6%) were diagnosed with a urinary tract malignancy, of whom 95 (97%) were older than 35 years of age. For these reasons, cystoscopy may be omitted in persons younger than age 35 years without risk factors or clinical suspicion for bladder cancer or urethral pathology (see Box 9-1).

Of note, blue-light cystoscopy using 5-aminolevulinic acid (ALA) or hexyl-aminolevulinic acid (HAL) instillation is approved by the U.S. Food and Drug Administration (FDA) for evaluation of patients with suspicion of papillary bladder cancer, but the studies supporting its use have been conducted in patients with known bladder cancer, thereby limiting generalizability to MH patients

(Davis et al, 2012; Malmstrom et al, 2012). In light of the small incremental risk associated with ALA or HAL and blue-light cystoscopy (rare anaphylactoid shock, hypersensitivity, pain, cystitis, dysuria, hematuria) and the risk for unnecessary biopsies compared to conventional white light cystoscopy, the AUA guideline recommends against using blue-light cystoscopy for evaluation of MH (Davis et al, 2012).

Upper Tract Imaging in the Diagnostic Evaluation of Hematuria

Multiphasic computed tomography (CT) urogram (i.e., CT with precontrast, nephrographic, and excretory series) is the imaging study of choice for the evaluation of asymptomatic MH (Vikram et al, 2009), because CT urography offers complete imaging of the urinary tract and has the highest sensitivity and specificity for detecting lesions of the renal parenchyma and the upper tracts. Nonetheless, CT urography does carry risks and may not be appropriate for all patients (e.g., pregnancy, iodinated contrast allergy, renal insufficiency). Indeed, in the setting of a contraindication to CT urogram, magnetic resonance urogram may be used as the upper tract study. Moreover, for patients with a contraindication to magnetic resonance imaging (e.g., pacemaker), as well as in the setting of significant renal function compromise (i.e., estimated glomerular filtration rate <30) when the administration of gadolinium risks nephrogenic systemic fibrosis, renal parenchymal imaging with noncontrast CT or ultrasound, in conjunction with retrograde pyelography to evaluate the calyces, renal pelvis, and ureters, may be most appropriate.

Urine Cytology and Urinary Biomarkers in the Diagnostic Evaluation of Hematuria

Urine cytologic examination is highly sensitive and specific for the detection of high-grade urothelial carcinoma, but sensitivity decreases significantly for low-grade urothelial carcinoma, resulting in an overall sensitivity of 15.8% to 54.5%, and specificity of 95.0% to 100% for bladder cancer detection (Miyanaga et al, 1999; Zippe et al, 1999; Chahal et al, 2001; Grossman et al, 2005; Steiner et al, 2008). Indeed, in a large study of patients with hematuria, the sensitivity and specificity of positive/suspicious/atypical cytology were 45.4% and 89.5%, respectively (Mishriki et al, 2013).

Meanwhile, although several urine biomarkers have been approved or cleared by the FDA for detection and surveillance of bladder cancer, few studies have been conducted to evaluate these markers in patients with MH who do not have a history of bladder cancer. Available assays include nuclear matrix protein-22 (NMP-22), bladder tumor antigen, fluorescence in situ hybridization (FISH) for abnormalities of chromosomes 3, 7, 17, and 9p21 (UroVysion [Abbott Molecular, Abbott Park, IL]) and immunocytology for carcinoembryonic antigen and mucin glycoproteins (ImmunoCyt [Scimedx, Denville, NJ] and CertNDx [PCLS, Rock Hill, SC]).

NMP-22 offers a potential advantage in management of patients with MH in that it is available as a point-of-care test. However, only two studies to date have focused on the asymptomatic patient with MH, with one finding a high sensitivity (90.9%), and the other, in a screening population, demonstrating very low sensitivity (6.0%). Specificity was moderate or high in both studies (76.3% and 82.5%, respectively) (Miyanaga et al, 1999; Steiner et al, 2008). Meanwhile, one study assessed FISH testing in patients with asymptomatic MH with a negative cytology and found that sensitivity and specificity may be high for upper tract tumors in this setting (Huang et al, 2012). A separate FISH study in asymptomatic MH patients (albeit without prior negative cytologic findings) showed sensitivity and specificity of 61% and 93%, respectively, for bladder tumors (Steiner et al, 2008). Immunocytology has been tested in the asymptomatic MH setting in one study of 189 patients (Schmitz-Drager et al, 2007). Here, eight bladder tumors were identified, of which seven were identified by

the ImmunoCyt test, for a sensitivity of 87%. However, studies in the urothelial carcinoma follow-up setting have found a far more modest sensitivity (68.1%) (Comploj et al, 2013). Finally, the multianalyte urine test CertNDx assesses several markers (mutant *FGFR3*, quantified matrix metalloproteinase-2 [MMP2], and hypermethylation of *TWIST1* and *NID2*). In a population of patients with hematuria (gross and microscopic) 50 years of age or older without diagnosis of bladder cancer, the sensitivity and specificity of this test were noted to be 87.9% and 56.3%, respectively (Karnes et al, 2012).

Together, because current evidence indicates that none of the available urinary biomarkers, including cytology, appear to be sufficiently sensitive or sufficiently validated to replace cystoscopy or imaging, these studies are not recommended in the initial evaluation of patients with asymptomatic MH (Davis et al, 2012). However, cytologic examination may be considered in patients with a negative initial workup in whom urothelial carcinoma is still suspected, as well as in patients with symptomatic MH.

Natural History of Microhematuria in Patients with a Negative Initial Evaluation

One of the most vexing questions in the management of MH is how to proceed in patients for whom the initial evaluation is negative. MH has been reported to resolve in approximately one third of these patients over a period of 3 months to several years (Yamagata et al, 1996; McGregor et al, 1998; Jaffe et al, 2001). Nevertheless, it is worth noting that these studies contained large proportions of younger patients, many of whom did not undergo a complete workup at any time, raising the possibility of persistent occult urologic disease. In a set of studies in which patients underwent further evaluation for MH after an initial negative evaluation, 41 malignancies were identified among 1475 patients (2.8%). However, the initial evaluations in these series were often incomplete, the follow-up evaluations were variable, and most of the malignancies were found in a study using CT urography in patients who were not evaluated by CT in the first evaluation (Davis et al, 2012).

In the absence of high-quality evidence, the AUA has issued three guidelines statements, based on expert opinion, pertaining to the follow-up of patients with an initial negative workup (Davis et al, 2012). The first two can be summarized as recommending following up annual urinalysis for 2 years after a complete negative hematuria workup and releasing the patient from care if the urinalyses confirm resolution of hematuria. The third statement recommends repeating the hematuria evaluation within 3 to 5 years in cases of persistent or recurrent asymptomatic MH or for development of symptoms or GH. We would add that patients with persistent or recurrent MH in the setting of an incomplete initial evaluation should have the evaluation completed or repeated.

KEY POINTS: EVALUATION OF PATIENTS WITH MICROHEMATURIA

- Evaluation of adults with microscopic hematuria includes a history and physical examination, renal function testing, and upper tract imaging for all patients.
- White light cystoscopy is recommended in the evaluation of asymptomatic MH for patients 35 years of age or older and/or those with risk factors for malignancy.
- CT urogram is the preferred imaging modality for the evaluation of hematuria.
- Urine cytologic examination and biomarkers are not indicated in the initial evaluation of asymptomatic MH.
- Patients with a negative complete evaluation can be released from care if subsequent urinalyses confirm resolution of MH. Re-evaluation should be considered in patients with persistent/recurrent MH and those with an incomplete initial evaluation.

SYMPTOMATIC MICROSCOPIC HEMATURIA

The differential diagnosis for symptomatic MH is equivalent to that for patients with asymptomatic MH. However, the risk for malignancy may be significantly higher than in asymptomatic MH (10.5% vs. 5.0% or less) (Sultana et al, 1996; Shephard et al, 2012). To the extent that symptoms help identify an obvious benign cause of hematuria (e.g., infection), and the hematuria resolves after management of this (culture-documented) benign cause, a complete workup can be avoided. Nevertheless, in situations in which an obvious benign cause is not definitively identified, the hematuria does not resolve after treatment of the benign cause, or the symptoms or other risk factors could be consistent with malignancy, full evaluation is recommended. Moreover, because the presence of symptomatic hematuria has been linked to an increased risk for malignancy, current AUA guidelines include several slight modifications to the recommendations for evaluation. Specifically, **cystoscopy is recommended in such patients, regardless of age** (Davis et al, 2012). Moreover, although routine cytology is not recommended as part of the routine evaluation for the asymptomatic patient with microscopic hematuria, **cytologic examination is considered an option in the setting of irritative voiding symptoms**, although cystoscopy should not be omitted even if the cytologic findings are negative (Davis et al, 2012).

GROSS HEMATURIA

The differential diagnosis for GH remains the same as outlined earlier for MH. Of note, however, **as the degree of hematuria increases, so does the likelihood of finding clinically significant lesions during evaluation**. That is, the difference between the yield of life-threatening lesions in patients with gross versus microscopic hematuria has been found to be highly significant (Mariani, 1989). Specifically, among patients with GH, 50% have been found to have a demonstrable cause, with 20% to 25% found to have a urologic malignancy, most commonly bladder cancer and kidney cancer (Lee and Davis, 1953; Khadra et al, 2000; Alishahi et al, 2002; Edwards et al, 2006).

Given the increased frequency with which clinically significant findings are associated with GH, the recommended evaluation in this setting is relatively uniform. That is, **patients presenting with GH in the absence of antecedent trauma or culture-documented UTI should be evaluated with a urine cytologic examination, cystoscopy, and upper tract imaging, preferably CT urogram**. Meanwhile, patients with GH in the setting of a culture-documented UTI should have the infection treated and then a follow-up urinalysis obtained to ensure clearance of the hematuria. The initial assessment for patients presenting with GH should include the history, physical examination, and laboratory studies recommended for patients with MH. Further, patients with GH must be assessed for hemodynamic stability with careful attention to vital signs, anemia with a complete blood count, and, for patients on anticoagulation, coagulation parameters to ensure that levels are within the therapeutic range. After initial stabilization, diagnostic evaluation should then proceed, with cause-specific management as outlined below.

Although clear recommendations are lacking for the follow-up of patients with GH who are found to have a nondiagnostic initial evaluation, the follow-up schedule as outlined for patients with asymptomatic MH may be used as a reference, with consideration given for a full repeat evaluation if episodes of GH recur.

HEMORRHAGIC CYSTITIS

Intractable hematuria localizing to the bladder, or hemorrhagic cystitis, may range in severity from a transient condition that quickly resolves after conservative management to a life-threatening condition requiring urgent intervention. Unfortunately, patients in this situation are often elderly and infirm, with medical comorbidities that complicate plans for care.

Hemorrhagic cystitis is characterized by diffuse inflammation and bleeding from the bladder mucosa (Rastinehad et al, 2007). Numerous causes for this condition have been described (Box 9-2), a few of which merit particular mention here. Bacterial infections, for example, are a common cause of GH, with symptomatic resolution typically noted after appropriate treatment. Meanwhile, viral-induced hemorrhagic cystitis may affect children and immunosuppressed adults particularly, as following renal or bone marrow transplantation. **BK virus, a member of the polyomavirus family, is the most common virus associated with hemorrhagic cystitis** (Gorczynska et al, 2005), and adenovirus, particularly types 11 and 35, has been correlated with hemorrhagic cystitis in children and renal transplant patients (Lee et al, 1996; Hofland et al, 2004). Treatment for viral hemorrhagic cystitis is primarily supportive, with hydration, diuresis, and bladder irrigation, although case reports of antiviral therapy exist (Rastinehad et al, 2007).

Hemorrhagic cystitis also may result from exposure to the oxazaphosphorine class of chemotherapeutic agents, specifically cyclophosphamide and ifosfamide. Indeed, hemorrhagic cystitis has been reported to occur in 2% to 40% of patients treated with cyclophosphamide (Rastinehad et al, 2007) and is dose dependent.

Medication induced
Penicillin and derivatives (via immune reaction)
Bleomycin
Danazol
Tiaprofenic
Allopurinol
Phensuximide
Methenamine mandelate
Acetic acid
Manifestation of systemic disease
Amyloidosis
Rheumatoid arthritis
Crohn disease

*Bleeding localized to bladder after diagnostic workup for gross hematuria with cystoscopy, urine cytology, and upper tract imaging is without clear cause of alternative bleeding source

Bladder toxicity results from renal excretion of the metabolite acrolein, which is produced by the liver and which stimulates bladder mucosal sloughing and subsequent tissue edema/fibrosis (O'Reilly et al, 2002). The onset of hematuria is typically within 48 hours of treatment (Cox, 1979; Stillwell and Benson, 1988). 2-Mercaptoethane sulfonate (mesna), which binds to acrolein and renders it inert, has been suggested for prophylaxis against cyclophosphamide-induced hemorrhagic cystitis (O'Reilly et al, 2002). Nevertheless, 10% to 40% of patients will develop the condition despite preventive treatment (Shepherd et al, 1991), and debate continues as to whether mesna is more effective at preventing hemorrhagic cystitis than hyperhydration with forced diuresis and/or continuous bladder irrigation (Shepherd et al, 1991; Vose et al, 1993).

Meanwhile, radiation therapy for pelvic malignancy represents another predisposing factor to hemorrhagic cystitis. Indeed, moderate-to-severe hematuria has been reported in approximately 5% of patients after pelvic radiotherapy, with onset between 6 months and 10 years after treatment (Corman et al, 2003). Mechanistically, radiation damages the vascular endothelium, thereby inducing subsequent inflammation, fibrosis, and ischemia, with tissue necrosis and mucosal sloughing occurring through progressive obliterative endarteritis (Hader et al, 1993; Bevers et al, 1995;

Chong et al, 2005). In the setting of such local vascular compromise, moreover, secondary infection frequently ensues, further compromising tissue healing (Del Pizzo et al, 1998).

Management of Hemorrhagic Cystitis

The management of hemorrhagic cystitis may occasionally be guided by the particular cause for the condition (e.g., treatment of infection), although in most cases no cause-directed therapy can be offered and instead a sequential approach, depending on the severity of the condition, should be undertaken (Fig. 9-2). Supportive management in the form of increasing urine output via hydration/diuresis, catheter placement with continuous bladder irrigation, and transfusion as needed represent the mainstay of first-line therapy and typically suffice for mild cases. If hematuria continues and/or clotting of the urine cannot be controlled with bladder irrigation, cystoscopy under anesthesia with clot evacuation and fulguration of discrete bleeding sites is then recommended.

For hematuria that persists despite such conservative measures, various agents have been investigated for bleeding control. Importantly, there is a lack of large, prospective trials reporting comparative treatment efficacy and safety. Nevertheless, an overview of these measures is warranted to facilitate a systematic approach to

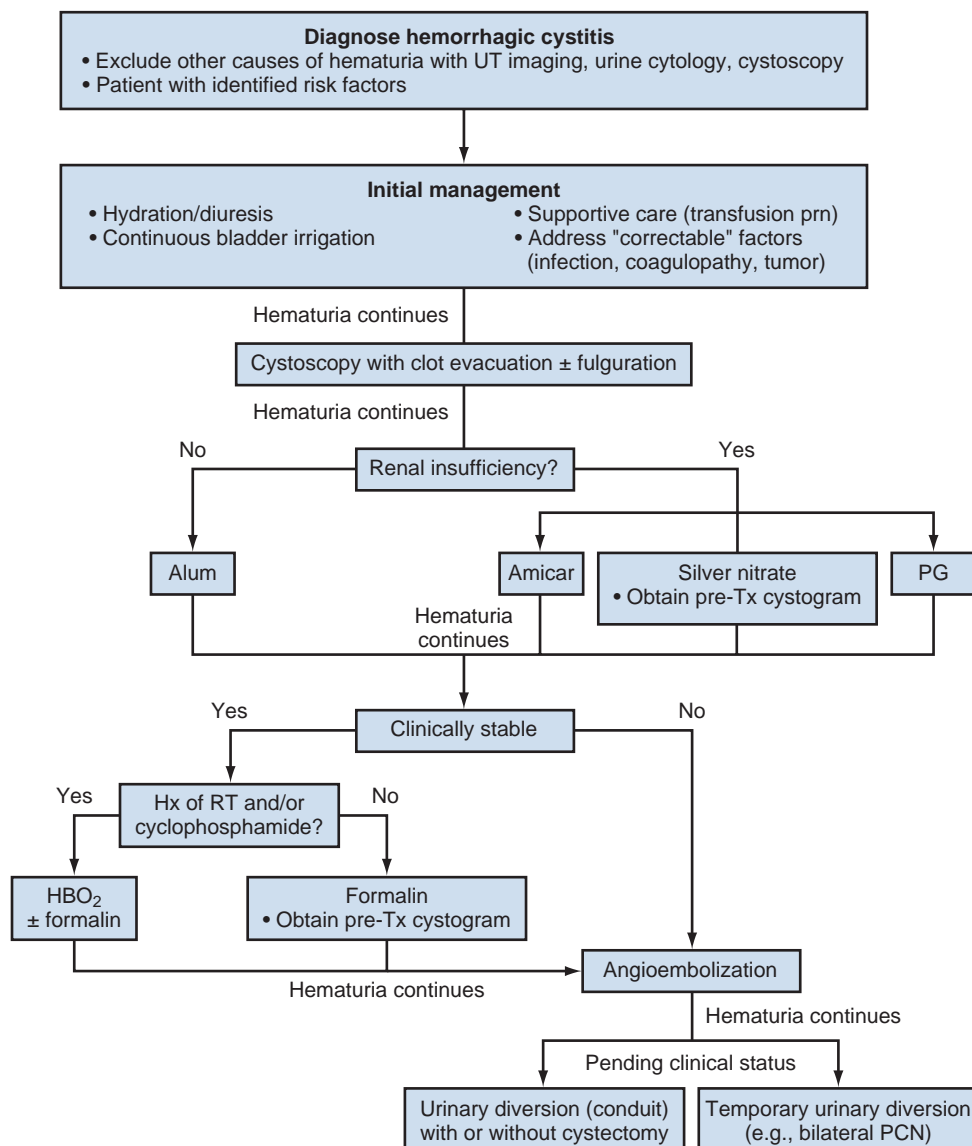

Figure 9-2. Management algorithm for patients with hemorrhagic cystitis. HBO₂, hyperbaric oxygen; Hx, history; PCN, percutaneous nephrostomy; PG, prostaglandin; Tx, treatment; UT, upper tract.

management. For one, alum (aluminum ammonium sulfate or aluminum potassium sulfate) may be dissolved in sterile water (50 g alum in a 5-L bag of sterile water [1% alum solution]) and then used to irrigate the bladder at a rate of 200 to 300 mL/hr. Through its action as an astringent at sites of bleeding, **alum may cause protein precipitation on the urothelial lining (Ostroff and Chenault, 1982) and thereby stimulate vasoconstriction and a decrease in capillary permeability (Choong et al, 2000).** In albeit small series to date, success rates of 66% to 100% have been reported after alum instillation (Choong et al, 2000; Abt et al, 2013). Although cell penetration and therefore overall toxicity of this agent are low (consisting mainly of suprapubic discomfort and bladder spasms), **systemic absorption may nevertheless occur and may result in aluminum toxicity, with consequent mental status changes, particularly among patients with renal insufficiency.** However, alum may be instilled without anesthesia and has an overall relatively favorable efficacy and safety profiles. Thus this agent may be considered for first-line intravesical therapy among patients with hemorrhagic cystitis failing initial supportive measures, particularly among those who are without renal insufficiency.

In addition, several alternative agents exist for intravesical instillation therapy. Prostaglandins (e.g., carboprost tromethamine [PGF₂-α]) (Abt et al, 2013) have been used intravesically for hemorrhagic cystitis, and although the precise mechanism of activity remains unclear, these agents are thought to cause vasoconstriction, platelet aggregation, and cytoprotection via mucous barrier regulation (Choong et al, 2000; Abt et al, 2013). Response rates of 50% to 60% have been noted (Choong et al, 2000; Abt et al, 2013), and in fact in a small (19 patients) prospective randomized study, no significant difference in efficacy was noted between PGF₂ and alum (Praveen et al, 1992). Notably, however, difficulties with PGF₂ access, storage, and high costs have limited generalized utility (Abt et al, 2013). Alternatively, silver nitrate may be instilled into the bladder, resulting in chemical coagulation at bleeding sites. A 0.5% to 1% solution is instilled for 10 to 20 minutes (Rastinehad et al, 2007). The potential for precipitation and upper tract obstruction with this agent led to the recommendation for a cystogram to rule out reflux before administration (Rastinehad et al, 2007).

Aminocaproic acid represents another intravesical treatment alternative. A lysine analogue, aminocaproic acid is a competitive inhibitor of activators of plasminogen, including urokinase, and thus interrupts fibrinolysis and the cascade that perpetuates hemorrhage (Garber and Wein, 1989; Stefanini et al, 1990; Abt et al, 2013). Continuous bladder irrigation with 200 mg aminocaproic acid/L of 0.9% normal saline has been described, with irrigation continued for 24 hours after hematuria resolves. Symptom resolution has been reported in up to 92% of patients (Singh and Laungani, 1992). The risk for thromboembolic events may be increased with this treatment, and, importantly, aminocaproic acid must be given only after the bladder has been rendered clot-free, because the agent will otherwise lead to the formation of hard clots difficult to eradicate from the bladder (Rastinehad et al, 2007).

Management for patients in whom hematuria remains refractory to the aforementioned measures is particularly challenging and is often guided by the patients' clinical status. That is, for clinically stable patients, intravesical formalin, a solution of formaldehyde that induces cellular protein precipitation and capillary occlusion (Choong et al, 2000), may be used. Control of bleeding has been reported in 80% to 90% of cases with formalin (Choong et al, 2000), which are relatively higher rates than what has been noted with other intravesical treatments. However, because formalin instillation may induce significant pain, administration under general or spinal anesthesia is recommended. Moreover, intravesical formalin therapy is associated with significant complications, including bladder fibrosis with associated decreased bladder capacity and ureteral stricturing with proximal hydronephrosis/renal injury (Choong et al, 2000; Abt et al, 2013). Thus pretreatment cystogram is recommended to exclude the presence of vesicoureteral reflux and/or bladder perforation (Donahue and Frank, 1989). If reflux is documented, placement of occlusive ureteral

catheters is recommended to limit upper tract exposure to the medication. Regardless, moreover, low concentrations of formalin (1% to 2%) should be used initially, because complication rates (albeit efficacy rates as well) have been linked to dosage (Donahue and Frank, 1989). Irrigation (with volumes up to 300 mL or to bladder capacity) (Choong et al, 2000) should be done under gravity, with the catheter no more than 15 cm above the pubic symphysis. Irrigation should be limited to 10 to 15 minutes and should be performed with the catheter on light traction to prevent urethral exposure, with care taken to protect all external areas of skin from exposure. Given the potential toxicities of formalin, together with the requirement for administration under anesthesia, this agent should be reserved for second-line therapy.

Another treatment option for patients with refractory hemorrhagic cystitis, particularly resulting from radiation therapy or cyclophosphamide-induced cystitis (Brastas et al, 2004), is hyperbaric oxygen (HBO₂) therapy. Treatment is carried out in a specially designed chamber and involves administration of 100% oxygen at a pressure of 2 to 3 atmospheres for approximately 90 minutes in 30 to 40 sessions (Bevers et al, 1995; Del Pizzo et al, 1998; O'Reilly et al, 2002). With this, local tissue oxygen tension increases and thus oxygen extraction by tissues increases, thereby diminishing edema and promoting neovascularization, critical steps in the wound healing process (Hader et al, 1993). Response rates to HBO₂ of 80% to 90% have been reported (Bevers et al, 1995; O'Reilly et al, 2002; Corman et al, 2003; Chong et al, 2005) and have been maintained up to 2.5 years after treatment (Weiss et al, 1994). However, with longer follow-up, most patients become symptomatic again, such that the 5-year complete response rate has been noted to be only 27% (Del Pizzo et al, 1998). Reported complications include claustrophobia (20%), otalgia (17%), and, rarely, seizures (O'Reilly et al, 2002).

For clinically unstable patients, as well as for patients with continued intractable bleeding, **internal iliac artery angioembolization represents a potential next step** in management. As reported in 1974 (Hald and Mygind, 1974), angioembolization may be performed unilaterally or bilaterally, even in debilitated patients, with relatively limited risk (Ward et al, 2003). Selective embolization of the anterior branch of the internal iliac artery bilaterally is typically required to achieve hemostasis. Care should be taken to avoid embolization of the posterior branch of the internal iliac artery, which, because of subsequent occlusion of the superior gluteal artery, may result in significant gluteal pain.

In the setting of failed angioembolization and other conservative approaches, **cystectomy with urinary diversion may be necessary to control bleeding.** Of note, pending the patients' clinical/comorbidity profile, consideration may be given to suprapubic urinary diversion alone, including bilateral nephrostomy tube insertion with occlusion of the ureters (Gonzalez et al, 2001), or ileal conduit diversion without cystectomy. The intention of such efforts is to decrease exposure of the hemorrhagic bladder to urokinase and thereby theoretically facilitate hemostasis (Rastinehad et al, 2007) while minimizing procedure-related morbidity. However, complications have been reported in up to 80% of patients with a retained bladder, including rehospitalization in 43% (Eigner and Freiha, 1990), suggesting that cystectomy should be performed at the time of urinary diversion if feasible. Unfortunately, such patients are typically ill and therefore in poor condition for surgery. As a result, complication rates may be even higher than what has been reported after cystectomy for bladder cancer.

HEMATURIA FROM PROSTATIC ORIGIN

As with hemorrhagic cystitis, hematuria from prostatic origin is a diagnosis made after a complete GH evaluation (including cytology, upper tract imaging, and cystoscopy) to confirm that no other source of hematuria exists. Varied causes exist for prostate-related hematuria, and the severity of such bleeding likewise may range from transient self-limiting episodes to continuous bleeding

KEY POINTS: HEMORRHAGIC CYSTITIS

- Oxazaphosphorine chemotherapeutic agents have been linked to the development of hemorrhagic cystitis through exposure of the metabolite acrolein to the urothelium.
- Alum may be used as a first-line intravesical therapy for hemorrhagic cystitis in patients without renal dysfunction.
- Formalin is a highly effective form of intravesical therapy for hemorrhagic cystitis. A cystogram should be obtained before therapy to ensure no vesicoureteral reflux.
- HBO₂ has been associated with response rates of 80% to 100% for patients with hemorrhagic cystitis.

resulting in the obstruction of urinary flow and in transfusion dependence. Most commonly, prostate-related bleeding is due to BPH, prostate-related infection (prostatitis), or prostate cancer (Fig. 9-3).

BPH represents the most common cause of prostate-related bleeding and has been cited as the most common cause of GH in men older than 60 (Borth and Nickel, 2006). In fact, BPH has been reported to be the only pathologic condition identified in approximately 20% of cases from hematuria studies (Hasan et al, 1994; Lynch et al, 1994). The cause for BPH-related hematuria has been thought to be increased prostatic vascularity resulting

from higher microvessel density in hyperplastic prostate tissue (Deering et al, 1995; Foley et al, 2000; Pareek et al, 2003; Borth and Nickel, 2006). This noted increase in microvessel density has in turn been linked to higher levels of vascular endothelial growth factor (VEGF) (Walsh et al, 2002; Pareek et al, 2003; Borth and Nickel, 2006).

Frequently, BPH-related hematuria episodes are mild and self-limiting, such that once the diagnosis has been established, expectant management with encouraged hydration can be undertaken. Interestingly, although GH has historically been considered an indication for surgery in the setting of BPH, increased understanding of the molecular pathway contributing to the pathophysiologic process (i.e., increased VEGF) has translated into the incorporation of what may be considered targeted medical therapy in the management of patients with BPH-related hematuria.

Specifically, because the pathophysiology of BPH-related bleeding has been postulated as increased cell proliferation stimulating increased vascularity, efforts to suppress prostate growth via androgen ablation have been explored (Marshall and Narayan, 1993; Foley et al, 2000). Both estrogens and antiandrogens have, in small case reports, been associated with decreased prostate bleeding, presumably through the repression of androgen-stimulated angiogenesis and the induction of programmed cell death within the prostate (Marshall and Narayan, 1993; Rittmaster et al, 1996). In particular, finasteride, a 5 α -reductase inhibitor that blocks conversion of testosterone to dihydrotestosterone and is a treatment for

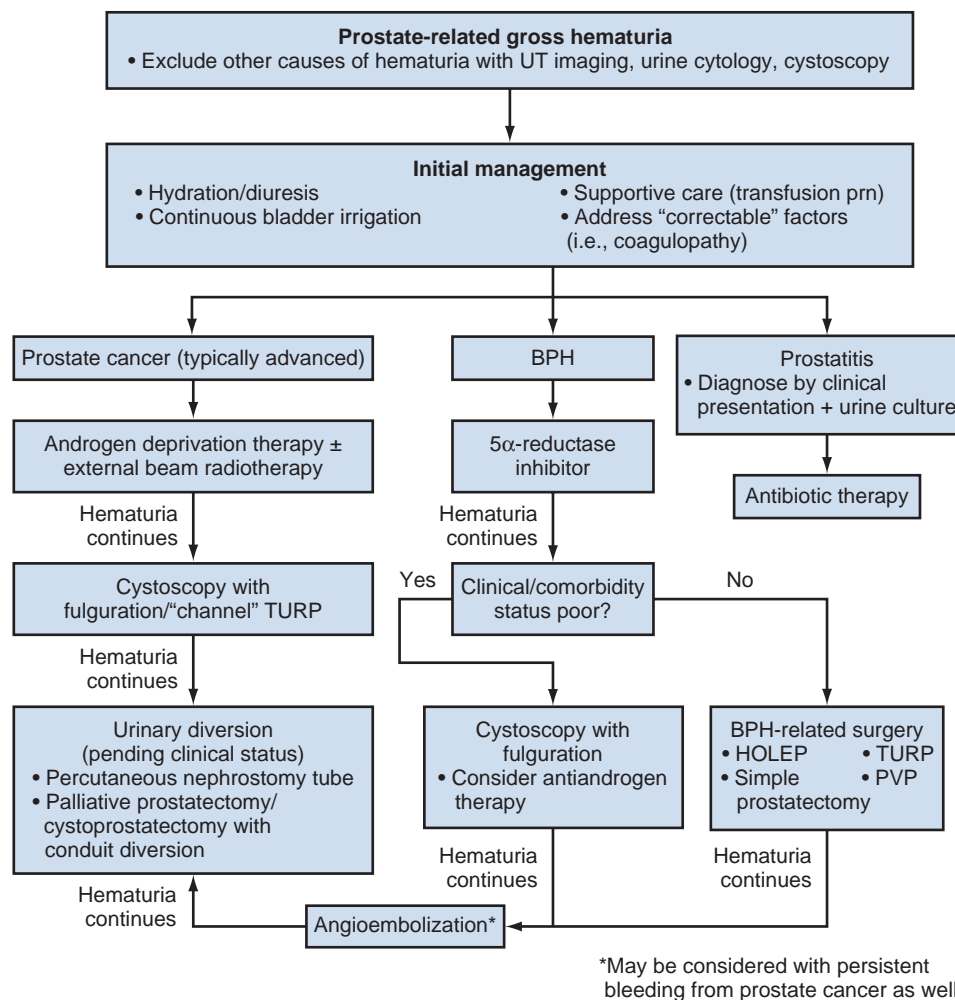

Figure 9-3. Management algorithm for patients with persistent hematuria of prostate origin. BPH, benign prostatic hyperplasia; HOLEP, holmium laser enucleation of the prostate; PVP, photovaporization of the prostate; TURP, transurethral resection of the prostate; UT, upper tract.

prostate-related outlet obstructive symptoms, has been investigated extensively for BPH-related bleeding. **Treatment with finasteride is associated with decreased VEGF expression (Pareek et al, 2003), prostate microvessel density (Pareek et al, 2003), and prostatic blood flow (Frauscher et al, 2003).**

Clinically, multiple series have demonstrated efficacy of finasteride for BPH-related hematuria, including in patients being treated with anticoagulation. Symptom improvement or resolution has been consistently noted in approximately 90% of patients (Puchner and Miller, 1995; Carlin et al, 1997; Miller and Puchner, 1998; Sieber et al, 1998; Kearney et al, 2002). A prospective randomized trial of finasteride versus expectant management in 57 patients with BPH-induced hematuria found that the rate of recurrent hematuria was significantly higher among patients in the control arm (63%) versus finasteride (14%) ($P < 0.05$), with 26% of patients in the control arm requiring surgery for bleeding versus none of the finasteride-treated patients (Foley et al, 2000). The onset of action for finasteride is variable, with improvement in bleeding noted from as short as 2 weeks to up to 9 months after initiating therapy. In addition, a randomized trial of finasteride versus cyproterone acetate versus watchful waiting demonstrated a significant decrease in recurrent hematuria in both the finasteride and in the cyproterone acetate cohorts, with no noted difference in efficacy between finasteride and cyproterone acetate in patients treated with this agent (Perimenis et al, 2002). Thus, although various forms of hormonal therapy remain options for BPH-related bleeding, the best data to date exist for 5 α -reductase inhibition, which likely entails the least side-effect profile as well.

In cases of BPH-bleeding in which patients have difficulty with bladder emptying and/or presence of clot, large-bore catheter placement with irrigation to evacuate all clot material from the bladder should ensue, followed by continuous bladder irrigation until the urine has cleared. If such measures are not sufficient to control bleeding, patients should be taken for endoscopic management under anesthesia, with clot evacuation and electric or laser cauterization. Although the variety of nonspecific intravesical therapies as are used in hemorrhagic cystitis (e.g., aminocaproic acid) have been suggested for use in this setting as well (Borth and Nickel, 2006), limited evidence exists to support the efficacy of these agents for BPH-related bleeding. Thus patients with persistent bleeding from BPH despite conservative therapies and/or endoscopic fulguration have traditionally been managed with transurethral resection of the prostate (TURP), particularly when additional indications for BPH surgery coexist. Although alternative forms of such endoscopic prostate tissue removal/destruction are available (e.g., photoselective vaporization of the prostate, holmium laser enucleation of the prostate) and even suprapubic/retropubic prostatectomy may be undertaken, the principle with all such interventions is to remove the hyperplastic and friable transition-zone prostate tissue. In cases with persistent bleeding despite TURP, selective angioembolization (Michel et al, 2002) and even radical prostatectomy or cystoprostatectomy should be considered, although, as with hemorrhagic cystitis, often such patients are poor surgical candidates because of comorbidity status.

Prostatitis, traditionally secondary to bacterial infection, also may result in GH. Indeed, a prior study reported hematuria as the manifesting symptom in 2.5% of men with prostatitis (Rizzo et al, 2003). The mechanism of hematuria in prostatitis is unclear and may be related to inflammation (Borth and Nickel, 2006). Management in this setting should consist of antibiotics when culture-documented bacterial prostatitis is present. Significant recurrent hematuria in the setting of nonbacterial prostatitis is relatively uncommon, and it has been suggested that such cases should be treated with antibiotics in addition to standard supportive measures (Borth and Nickel, 2006).

Meanwhile, hematuria from prostate cancer typically results in cases of significantly locally advanced tumors, often with bladder base/trigonal invasion. Indeed, hematuria has been noted to be the most common local symptom among patients with advanced symptomatic prostate cancers (Din et al, 2009). Importantly, the hematuria in these patients, particularly in those who

have previously received radiation therapy in the management of their prostate cancer, should be confirmed with endoscopic evaluation to be from a prostate source and not, for example, as a result of hemorrhagic cystitis or secondary bladder malignancy. Unfortunately, these tumors are typically invasive of the bladder and/or pelvic sidewall (T4) and the patients are often elderly and unwell. Thus treatment is primarily with palliative intent. Initial conservative measures, including catheter drainage with or without continuous bladder irrigation, suffice for most cases of mild prostatic bleeding. For patients in whom hematuria is not acutely life-threatening, palliative external beam radiotherapy with or without androgen deprivation therapy may be administered. Indeed, one series reported that hematuria from advanced prostate cancer responded to palliative radiation in 81% of patients at 6 weeks after treatment; however, durable symptom control was limited, such that the response rate 7 months after treatment in these patients was only 29% (Din et al, 2009). Among patients who are not candidates for local therapy, as well as among patients in whom disease has recurred after previous local therapy, androgen deprivation therapy may resolve the hematuria (Marshall and Narayan, 1993) by decreasing prostate vascularity (Kaya et al, 2005).

In the situation of persistent hematuria with prostate cancer, and in particular in the setting of bladder outlet obstruction, cystoscopy under anesthesia with fulguration and/or limited, or channel, transurethral resection of prostatic tissue should be undertaken. Moreover, selective internal iliac artery embolization, as has been reported for severe post-TURP bleeding (Barbieri et al, 2002; Michel et al, 2002), may be considered, although data on this approach in the setting of prostatic malignancy are scant. Ultimately, if bleeding persists or escalates, consideration should be given to urinary diversion, which initially may be attempted with percutaneous nephrostomy tube insertion. With continued prostate hemorrhage, palliative extirpative surgery, which may be in the form of radical prostatectomy, but more typically requires cystoprostatectomy and conduit diversion, should be considered pending patients' clinical and comorbidity status.

KEY POINTS: HEMATURIA FROM PROSTATIC ORIGIN

- BPH represents the most common cause of GH in men older than 60 years.
- 5 α -Reductase inhibitors may be used for BPH-related GH.
- Androgen deprivation may be effective for patients with locally advanced prostate cancer with GH.
- Angioembolization and/or urinary diversion represent salvage options for management for patients with refractory hematuria, pending clinical status.

URETHRAL BLEEDING

Urethral bleeding (urethrorrhagia) is defined as bleeding emanating from the urethra at a point distal to the bladder neck, occurring separate from micturition (Gontero, 2013). A careful history and physical examination may help elucidate whether the source of bleeding is truly from the urethra as opposed to other sites within the lower urinary tract. For example, blood at the urethral meatus in the absence of volitional micturition, initial hematuria, or blood at the start of urination frequently implies pathologic processes distal to the external urinary sphincter. Of note, in women, differentiating urethral bleeding from that of gynecologic origin based on history alone may be challenging and pelvic examination is typically necessary to clarify the site of origin (Sandhu et al, 2009). Importantly, retrograde urethrogram and cystourethroscopy remain the mainstays for diagnosis in patients with suspected urethral bleeding, because direct visualization permits identification of pathologic processes in the urethra and biopsy and fulguration allow for histologic characterization and cessation of bleeding.

Causes of urethral bleeding are best classified by gender (**Box 9-3**). In men, trauma to the urethral epithelium represents the most common cause of urethral bleeding. For example, blunt trauma via straddle injury, kick to the perineum, or pelvic fracture often manifests with bleeding and concurrent urinary retention (**Mundy and Andrich, 2011**). Perineal or penile bruising, accompanied by a hematoma, often is a clear indication of injury related to trauma. Retrograde urethrography is essential in instances of trauma when a urethral injury is suspected (**Avery and Scheinfeld, 2012**). Meanwhile, a history of foreign body insertion in patients with hematuria may necessitate imaging to ensure no residual foreign elements remain that could perpetuate bleeding or result in subsequent calculus formation (**Rahman et al, 2004**). Particular mention should be made to the evaluation of bloody urethral discharge and/or hematuria occurring in patients with a penile fracture. In this setting, prompt evaluation via retrograde urethrography or cystoscopy should be undertaken to evaluate for a urethral injury and to identify the nature and location of the injury before surgical exploration (**Avery and Scheinfeld, 2012**).

Urethritis refers to infection or inflammation of the epithelial lining of the urethra and has been reported secondary to bacterial or viral infection, chemical irritants (i.e., spermicidal jelly), and, rarely, autoimmune systemic conditions (human leukocyte antigen B27 [HLA-B27] Reiter syndrome). Urethral discharge on palpation may be noted with urethritis in men. Urine microscopy and cultures, as well as urethral swabs for causative organisms, represent essential components of the evaluation.

Urethral tumors are rare, although blood per meatus may be a manifesting sign in patients with urothelial carcinoma, specifically in men who have undergone a radical cystectomy with urethra still in situ (**White and Malkowicz, 2010**). At the same time, urethral caruncles are benign urethral lesions typically originating from the posterior lip of the urethra, most commonly found in postmenopausal women (**Conces et al, 2012**). These lesions are thought to arise from prolapse of distal urethra as a consequence of estrogen deficiency. In addition to the classic presentation

of dysuria, dyspareunia, and dribbling, women with a urethral diverticulum also may report intermittent episodes of bleeding, and urethral discharge may be noted on examination.

HEMATURIA ORIGINATING FROM THE UPPER URINARY TRACT

Hematuria emanating from the upper urinary tract is frequently asymptomatic, although macroscopic bleeding with clots can result in subsequent ureteral obstruction, with patients experiencing “clot colic,” as well as anemia, and even rarely hemodynamic instability (**Lano et al, 1979**). Most often, hematuria from the upper tract manifests as total hematuria, or bleeding throughout the duration of the urinary stream (**Mazhari and Kimmel, 2002**), and may be characterized by wormlike clots passed per urethra. A variety of causes can result in bleeding from the upper tract (**Box 9-4**), with

BOX 9-3 Differential Diagnosis for Urethral Bleeding

MALE

Trauma

- Blunt (straddle injury, kick to perineum)
- Penetrating (foreign body insertion, failed urethral catheterization)
- Intercourse related (penile fracture, masturbation)

Urethritis

- Bacterial (gonococcal, nongonococcal)
- Viral
- Chemical
- Autoimmune (Reiter syndrome)

Malignancy

- Urothelial carcinoma
- Squamous cell carcinoma (meatus/glans)

Condyloma

- Xanthogranulomatous pyelonephritis
- Renal tuberculosis
- Fungal infection

Obstruction

- Ureteropelvic junction obstruction
- Ureteral stricture

Nephrolithiasis

Malignancy

- Renal cortical tumors (renal cell carcinoma, benign tumors)
- Upper tract urothelial carcinoma

Fibroepithelial polyp

Vascular diseases

- Renal arteriovenous malformations (congenital, acquired)
- Iliac arterio-ureteral fistula
- Renal artery aneurysm (especially ruptured)
- Renal artery pseudoaneurysm
- Renal artery and/or vein thrombosis
- Hemangioma
- Atheroembolic disease
- Nutcracker syndrome
- Loin-pain hematuria syndrome

Trauma

- Blunt
- Penetrating
- Lateralizing essential hematuria

the most common causes of hematuria from the upper urinary tract including stones, trauma, and malignancy. The evaluation and management of these entities is described elsewhere. Herein, we highlight several particularly salient, albeit less frequent, causes of upper tract hematuria.

Medical Renal Disease

Glomerular diseases are a constellation of acquired or inherited conditions in which the glomeruli are damaged. Consequences include loss of RBCs and protein in the urine, with the clinical sequelae of hematuria, hypoproteinemia with associated edema, and reduced glomerular filtration rate. **Urinary findings suggestive of a glomerular cause include the presence of RBC casts in the urinary sediment, dysmorphic RBCs, and proteinuria (Yun et al, 2004).** Common acquired causes of glomerular diseases are covered in Chapter 46.

Meanwhile, tubulointerstitial diseases broadly refer to kidney diseases affecting structures in the kidney outside the glomerulus. For example, sickle cell nephropathy is associated with sickle cell disease, whereby sickled erythrocytes decrease medullary blood flow, causing local ischemia, microinfarction, and papillary necrosis (Pham et al, 2000). Analgesic nephropathy can likewise cause renal papillary necrosis and subsequently chronic interstitial nephritis. Percutaneous renal biopsy may be a valuable diagnostic modality when a suspicion exists for glomerular or tubulointerstitial causes of hematuria.

Vascular Conditions Affecting the Urinary Tract

A variety of vascular conditions can cause hematuria. For example, ureteroiliac artery fistula is an uncommon but potentially life-threatening cause of hematuria. **Predisposing factors include pelvic or vascular surgery, pelvic irradiation, extensive ureteral mobilization, and chronic ureteral stenting (Muraoka et al, 2008).** With regard to management, high mortality rates have been reported with surgical repair of ureteroiliac fistulas, and as such angiographic localization with vascular stenting has become the current preferred management approach (Keller et al, 1990). Renal arteriovenous malformations (AVMs), meanwhile, are abnormal communications between intrarenal arterial and venous systems, with congenital and acquired (iatrogenic) causes. **Acquired AVMs account for 75% of such cases and have been associated with renal biopsy, renal surgery (partial nephrectomy, nephrolithotomy), and trauma (Muraoka et al, 2008).** Arteriography with selective angioembolization is considered the primary diagnostic and therapeutic option for suspected renal AVMs, affording symptom resolution with maximal preservation of functional renal parenchyma. Thus **expeditious angiography should be considered for patients with a recent history of a renal procedure presenting with GH.** The goal of AVM embolization is eradication of the site where abnormal arterial and venous communication exists. Renal artery aneurysms, moreover, may be related to connective tissue disorders and are generally asymptomatic. Hypertension may be present in up to 90% of affected persons, and dissecting aneurysms may cause flank pain with GH. Renal artery aneurysms and pseudoaneurysms are generally managed via endovascular approaches in the hemodynamically stable patient, whereas surgical intervention is typically necessary in the unstable patient (Mohan and Stephens, 2013).

Additionally, **"nutcracker syndrome" (i.e., renal vein entrapment syndrome)** is defined as the compression of the left renal vein between the abdominal aorta posteriorly and the superior mesenteric artery anteriorly. Hematuria has been postulated to occur as a result of increase in left renal vein pressure causing small-volume rupture of thin-walled capillaries into the collecting system (Wolfish et al, 1986). Left renal vein transposition, superior mesenteric artery transposition, and nephrectomy have been described as surgical approaches for management of this condition (Hohenfellner et al, 2002). More recently, endovascular stenting to maintain a patent renal vein has been reported as well.

Lateralizing Essential Hematuria and the Evaluation of Upper Urinary Tract Bleeding

Lateralizing essential hematuria, also termed *benign essential hematuria* or *chronic unilateral essential hematuria*, is defined as macroscopic hematuria cystoscopically localized to one side of the urinary system (Nakada, 2003). Patients have typically had normal prior radiographic studies. Although rare, manifestations of lateralizing essential hematuria may range from minimally symptomatic GH to clot retention and anemia (Nakada, 2003). The differential diagnosis for this entity is as noted earlier for upper tract bleeding (see Box 9-4), although in many such cases no identifiable cause can be determined.

Cystoscopy at the time of bleeding may allow lateralization of the source of hematuria. Subsequently, in the absence of a clear cause for bleeding localized to the upper tract in a patient with lateralizing essential hematuria, direct endoscopic inspection with ureteropyeloscopy is recommended as a diagnostic and potentially therapeutic modality (Nakada, 2003). **Critical components of diagnostic ureteropyeloscopy include the judicious use of guidewires (to avoid inadvertent urothelial injury), low-pressure irrigation, and systematic evaluation of all calices from a superior-to-inferior approach (Ankem and Nakada, 2006).** Biopsy samples can be obtained for lesions suspicious for malignancy, and fulguration of such tumors or other noted sources of bleeding (i.e., hemangioma) can be accomplished as well.

KEY POINTS: URETHRAL BLEEDING AND HEMATURIA ORIGINATING FROM THE UPPER URINARY TRACT

- Urethral bleeding should be suspected with blood at the meatus and/or initial hematuria.
- A concern for traumatic urethral injury should prompt retrograde urethrogram.
- Urinary findings suggestive of a glomerular cause include the presence of RBC casts in the urinary sediment, dysmorphic RBCs, and proteinuria.
- In patients with GH after a recent renal procedure, expeditious angiography should be considered to allow for the diagnosis and management of renal AVM.

Preoperative Preparation

In the Operating Room

Strategic Placement of Operative Team and Equipment

Performing the Procedure

Physiologic Considerations in the Adult

Complications and Troubleshooting in Laparoscopic and Robotic Surgery

Training and Practicing Laparoscopic and Robotic Surgery

Conclusion

More than 100 years ago the “father of modern medicine,” Sir William Osler, challenged surgeons to perpetually refine their craft, stating, “Diseases that harm require treatments that harm less.” In pursuit of this noble goal, the urologists of the 20th century brought us great achievements in our field, but it has been over the past 25 years, in particular, that the specialty of minimally invasive urology has become predominant. The earliest techniques that laid the foundation for modern laparoscopic and robotic urologic procedures were developed at academic institutions throughout the world and have continuously been validated and improved. Subsequently, an increasing number of multi-institutional studies have emerged comparing laparoscopic and robotic procedures with their open surgical counterparts and showing equivalent efficacy and acceptable efficiency, as well as the distinct advantages of decreased postoperative pain, better cosmesis, faster recovery, a shorter hospital stay, and, in many cases, lower cost. Indeed, it has become increasingly clear that the objectives of many open urologic surgeries, be it of the adrenal gland, kidney, ureter, bladder, prostate, or lymph nodes, can now be achieved with minimally invasive surgery with less patient injury and suffering. Therefore, whereas open surgery has had a steadily diminishing role in the treatment of urologic diseases, laparoscopic and robotic surgery have moved into the mainstream of urologic surgery, and knowledge of the required principles and techniques is essential for the practicing urologist. This chapter is intended to provide a basic foundation of knowledge on which the aspiring minimally invasive urologist can build.

PREOPERATIVE PREPARATION

Patient Selection and Contraindications

Careful patient selection and identification of possible relative and absolute contraindications to laparoscopic and robotic procedures are vital to a successful outcome. To this end, a meticulous past history, focusing on prior surgeries, and physical examination, detailing the location and extent of all abdominal scars, are the initial steps in patient evaluation.

Age- and health-based laboratory studies, an electrocardiogram, and a chest radiograph should be obtained according to the same criteria established for any other significant surgical procedure that is undertaken with general anesthesia.

In patients with severe chronic obstructive pulmonary disease (COPD), further studies (i.e., arterial blood gases and pulmonary function tests) are required because of the physiologic effects of the CO₂ pneumoperitoneum. Cardiac arrhythmias should be evaluated

and treated preoperatively because hypercarbia and the resulting acidosis, from the pneumoperitoneum, may have adverse effects on the myocardium, thereby exacerbating any preexisting myocardial instability.

Contraindications to laparoscopic surgery include uncorrectable coagulopathy, intestinal obstruction unless there is an intention to treat, significant abdominal wall infection, massive hemoperitoneum or hemoretroperitoneum, generalized peritonitis, and suspected malignant ascites. Select circumstances in which laparoscopy is being contemplated necessitate careful risk-benefit analysis and detailed and specific informed consent with the patient. The following conditions may portend potential difficulties with a laparoscopic approach.

Morbid Obesity

Laparoscopic procedures in morbidly obese patients are technically challenging. Difficulties may include inadequate length of instruments, decreased range of motion of trocars and instruments, need for higher pneumoperitoneum pressures to elevate the abdominal wall, and poor anatomic orientation owing to excessive amounts of adipose tissue. Traditionally, these difficulties translated into a higher rate of associated complications (Mendoza et al, 1996; Anast et al, 2004; Parker et al, 2008; Aboumarzouk et al, 2012). However, in comparison to open surgery it has been found that the laparoscopic approach to renal and adrenal procedures actually has several advantages. Studies have shown for laparoscopic adrenalectomy and nephrectomy in obese patients that the laparoscopic group had significantly superior outcomes regarding blood loss, resumption of oral intake and ambulation, narcotic analgesic requirements, median hospital stay, and convalescence compared with the open approach (Fazeli-Matin et al, 1999; Fugita et al, 2004; Kapoor et al, 2004; Shuford et al, 2004). These findings have been confirmed for complicated procedures such as laparoscopic and robotic partial nephrectomy (Colombo et al, 2007; Romero et al, 2008; Isac et al, 2012) and laparoscopic nephroureterectomy (Brown et al, 2008).

With regard to laparoscopic and robotic radical prostatectomy in obese men, it has been found that although the operation can be performed without compromising pathologic outcomes, obese patients have a greater risk of perioperative complications (26% vs. 5%) (Ahlering et al, 2005).

Extensive Prior Abdominal or Pelvic Surgery

When extensive intra-abdominal or pelvic adhesions are suspected, careful consideration must be given to the possible site of Veress

needle insertion as well as to obtaining open access with a Hasson-style cannula. The Palmer point (subcostal in the midclavicular line on the left side) is the preferred site for Veress needle insertion when extensive intra-abdominal adhesions are suspected (Palmer, 1974). Alternatively, in these patients a retroperitoneal approach may be preferable to a transperitoneal approach or the procedure can be initiated retroperitoneally and the peritoneum then entered (Cadeddu et al, 1999).

Pelvic Fibrosis

Pelvic fibrosis caused by previous peritonitis, pelvic surgery, or extensive endometriosis may constitute a severe technical challenge to the laparoscopic surgeon when surgery of the lower urinary tract is indicated. Similar problems may be encountered when trying to perform pelvic lymph node dissection in patients who have a hip prosthesis; leakage of the polymethyl methacrylate cement can create a dense inflammatory reaction and fibrosis in the adjacent pelvis (Cooper et al, 1997).

Organomegaly

Known or preoperatively diagnosed organomegaly (e.g., hepatomegaly or splenomegaly) necessitates a cautious approach when obtaining the pneumoperitoneum. The site of Veress needle insertion must be chosen at a safe distance from any enlarged organs, or, preferably, open access with the Hasson cannula may be considered.

Ascites: Benign Cause

Patients with severe ascites are under increased risk of injury to the bowel owing to closer proximity of bowel loops to the anterior peritoneum. In addition, a watertight wound closure is required and a firm wound dressing should be applied to prevent prolonged postoperative leakage.

Pregnancy

Initial access to the abdomen must be obtained at a safe distance from the fundus of the gravid uterus. Therefore, trocar placement is usually performed more cephalad on the abdominal wall, depending on the fundus of the uterus. The left upper quadrant in the subcostal midclavicular line (i.e., Palmer point) is often the preferred site of access. Prolonged intra-abdominal pressures of 15 mm Hg or greater may result in hypotension owing to significantly reduced venous return because the vena cava is already mechanically compromised by the enlarged uterus. Prolonged CO₂ pneumoperitoneum, which may result in maternal hypercarbia and acidosis with subsequent adverse effects on the fetus, should be avoided. Accordingly, a working pneumoperitoneum of 10 to 12 mm Hg is recommended in the pregnant patient. **The second trimester is a preferred time for necessary surgery, given the completion of fetal organogenesis and reduced chance of inducing labor.**

As pregnancy progresses beyond the 20th week, the possibility of performing laparoscopic procedures decreases significantly, correlating with the increasing size of the gravid uterus. Of note, both laparoscopic nephrectomy and adrenalectomy have been successfully accomplished in pregnant women (Nezhat et al, 1997; O'Connor, et al, 2004; Sainsbury et al, 2004).

Hernia

A diaphragmatic hernia may result in leakage of a significant amount of CO₂ into the mediastinum, which, although rarely noted, may eventually result in clinical problems such as respiratory compromise or cardiac tamponade (e.g., pneumopericardium) (Knos et al, 1991).

Any evidence of uncorrected or surgically corrected umbilical hernia or abdominal wall hernia should rule out these sites for obtaining a pneumoperitoneum.

Iliac or Aortic Aneurysm

Significant aneurysms warrant evaluation by the vascular surgeon. If the aneurysm does not require immediate surgical correction, insertion of the Veress needle should be performed in the left upper quadrant to stay well away from the area of the aneurysm. Of course, open access with the Hasson technique can be used alternatively. Insertion of accessory trocars must be done under strict endoscopic control to avoid the area of the aneurysm.

Bowel Preparation

For extraperitoneoscopy and retroperitoneoscopy, no bowel preparation is necessary. Similarly, for transperitoneal laparoscopic or robotic procedures *not* involving the use of bowel segments for urinary tract reconstruction, a mechanical bowel preparation is not necessary. A recent large-scale propensity score-matched analysis demonstrated no benefit for mechanical bowel preparation in operative time, postoperative stay, or overall complications for patients undergoing laparoscopic nephrectomy (Sugihara et al, 2013a). Likewise, the same group found no benefit to mechanical bowel preparation in patients undergoing laparoscopic radical prostatectomy in terms of complications, operative time, and postoperative length of stay (Sugihara et al, 2013b).

More recently, emphasis has been placed on “fast-tracking” patients in an effort to streamline care and decrease length of hospital stay. Breda and associates (2007) found that a modified bowel preparation and avoidance of narcotic analgesics postoperatively (with routine administration of ketorolac) was instrumental in achieving a hospital stay of 1.1 days for patients undergoing laparoscopic donor nephrectomy. The bowel preparation consists of clear liquids for 2 days before surgery, two bottles of magnesium citrate the day before surgery, an enema the night before surgery, and nothing to eat after midnight (Breda et al, 2007).

The need for a full mechanical and antibiotic bowel preparation is subject to question and becomes an issue only if one anticipates encountering dense intra-abdominal adhesions or if the surgery involves entering the bowel. However, emerging literature suggests no benefit to a full mechanical bowel preparation for patients undergoing radical cystectomy with creation of ileal conduit or orthotopic neobladder (Hashad et al, 2012; Large et al, 2012; Raynor et al, 2013).

Preparation of Blood Products

Serum type and screen are sufficient for laparoscopic and robotic procedures with a low chance of major hemorrhage. Procedures such as laparoscopic radical nephrectomy and nephroureterectomy have a low rate of transfusion (3% to 12%), with an estimated average blood loss in the range of 106 to 255 mL (Ono et al, 1999; Dunn et al, 2000; Jeschke et al, 2000; Shalhav et al, 2000). Similarly, the transfusion rate with laparoscopic or robotic radical prostatectomy is low (2.5% at experienced centers) (Guillonneau and Vallancien 2000; Ahlering et al, 2004).

More extensive laparoscopic robotic procedures (e.g., partial nephrectomy, radical cystectomy, radical nephrectomy with inferior vena cava thrombectomy), especially early in one's experience, should be managed like any other major open surgical procedure, with packed red blood cells available before surgery. With greater experience, a type and screen may suffice for certain more extensive procedures (e.g., partial nephrectomy) because the risk for transfusion is low (6% to 7%) (Ghani et al, 2014).

IN THE OPERATING ROOM

Setup of the Operating Room

The operating room has to provide enough space to accommodate all necessary personnel and the equipment required by both the surgeon and the anesthesiologist. Positioning of equipment, surgeon, assistants, nurses, anesthesiologist, and other support staff

BOX 10-1 Instrumentation Checklist for Making a Skin Incision for Obtaining the Pneumoperitoneum

1. Irrigation-aspiration unit is working.
2. Electrosurgical unit is working.
3. CO₂ tank is full, with extra CO₂ tank in the room.
4. Camera is white balanced, and light source is working.
5. Insufflation is checked for flow and response to kinking of the tubing.
6. Veress needle is checked for flow and proper tip retraction.

KEY POINTS: PREOPERATIVE PREPARATION

- Careful patient selection and identification of possible relative and absolute contraindications are vital to a successful outcome of laparoscopic and robotic procedures. To this end, a meticulous past history, focusing on prior surgeries, and physical examination, detailing the location and extent of all abdominal scars, are the initial steps in patient evaluation for possible minimally invasive surgery.
- Contraindications to laparoscopic surgery include uncorrectable coagulopathy, intestinal obstruction unless treatment is intended, significant abdominal wall infection, massive hemoperitoneum or hemoretroperitoneum, generalized peritonitis, and suspected malignant ascites.

should be clearly defined and established for each laparoscopic or robotic case. All equipment must be fully functional and in operating condition before any laparoscopic procedure is started (Box 10-1). A separate tray with open laparotomy instruments must be ready for immediate use in the event of complications or problems necessitating emergent open surgery.

Patient Positioning

Positioning of the patient depends primarily on the procedure to be performed. In the supine position the arms can be tucked snugly at the sides or rest on specially designed sleds. In the Trendelenburg or lateral position, tape and security belts applied across the chest and thighs provide safe and stable positioning of the patient. In the lateral position, all bony prominences in contact with the table must be carefully padded; likewise, the point of contact between any of the positioning straps and the hip or shoulder should be padded. In the lateral position, the bottom leg is flexed approximately 45 degrees while the upper leg is kept straight; pillows are placed between the legs as a cushion and also to elevate the upper leg so that it lies level with the flank, thereby obviating any undue stretch on the sciatic nerve. Pads should be placed between the table and the knee and ankle of the lower leg because these are high-pressure areas. In the lateral decubitus position an axillary roll should be used. Application of an active warming system may prevent hypothermia, should a lengthy laparoscopic procedure be anticipated.

A host of new advances in padding and table-mounted accessories are now available, but none has been conclusively demonstrated to significantly reduce pressure on the patient's flank in the lateral position. Researchers at the University of California, Irvine, showed that women have significantly lower interface pressures than men (Deane et al, 2008). A body mass index (BMI) greater than or equal to 25, use of a kidney rest, and full-table flexion as opposed to half-table flexion were all associated with increases in interface pressures; of these, **use of the kidney rest was believed to be the most detrimental and its use beyond 20 to 30 minutes was discouraged.** Therefore, male patients with a BMI of 25 or higher

undergoing laparoscopic surgery in the lateral position with the kidney rest elevated and the table completely flexed are at highest risk of developing rhabdomyolysis from flank pressure. In this study the unaugmented operating table mattress was superior to egg crate or gel padding as an augmenting surface material; of note, egg crate padding was equal or superior to the more expensive gel padding.

Table-mounted accessories for all major commercial operating room tables now exist that aid in safely and effectively positioning patients in the lateral decubitus position and in the prone position. For laparoscopic or robotic procedures on the pelvis, the patient can be placed in Trendelenburg position with the legs on split-leg positioners (Fig. 10-1A on the Expert Consult website) or in Allen stirrups (Fig. 10-1B on the Expert Consult website). **Shoulder supports or braces should never be used in this position owing to the risk of brachial nerve injury.**

Prophylaxis and Other Preparations

Pneumatic compression stockings can be applied for antiembolic prophylaxis. In addition, the administration of 5000 units of subcutaneous heparin preoperatively is also an option. In higher-risk patients, such as the morbidly obese, both may be considered (see the discussion of early postoperative complications). Before laparoscopic or retroperitoneoscopic procedures, placement of a Foley catheter should be performed to allow for accurate measurement of urine output, to decompress the bladder to improve visibility and working space, and to reduce the risk of injury with pelvic procedures. Similarly, when needed, a nasogastric or orogastric tube can be inserted to improve the working space available in the upper abdomen.

STRATEGIC PLACEMENT OF OPERATIVE TEAM AND EQUIPMENT**Standard Laparoscopic Carts**

Traditionally, the mandatory hardware for laparoscopic procedures (monitor, light source, insufflator) is located on carts or "towers" that can be rolled around the operating room and adapted to various types of surgical procedures and approaches (Fig. 10-2A on the Expert Consult website). The main laparoscopic cart should contain the insufflator, light source, camera controls, and any recording device. Ideally, the insufflator should be placed at the surgeon's eye level to allow continuous monitoring of the CO₂ pressure.

Integrated Endoscopy Systems

More recently, most major manufacturers of endoscopy equipment offer "integrated" systems that consist of flat panel displays and equipment towers that are mounted on adjustable ceiling booms (see Fig. 10-2B on the Expert Consult website). This allows the display monitors to be suspended over the patient and placed directly in front of the surgeon at any height or angle. This feature may reduce eye and body strain. Furthermore, the tower containing the light source, camera system, and insufflator can be placed in any area around the patient depending on the operation at hand.

Robotic Systems

Currently, the only robotic surgical system in widespread use for laparoscopic surgery is the da Vinci Robotic System (Intuitive Surgical, Sunnyvale, CA). The three major components of the system are the robotic tower (i.e., patient-side cart) to which are attached the instruments that are mechanically manipulated within the patient; a surgeon's console, which is the workstation at which the surgeon sits to manipulate the robotic instruments; and finally the ancillary vision cart, which supports a flat screen monitor, an insufflator, a light source, and components of the camera system (Fig. 10-3 on the Expert Consult website). Additional monitors can be linked

Figure 10-1. A, Split-leg positioners. B, Allen stirrups.

Figure 10-2. A, A standard laparoscopic cart. B, An integrated laparoscopic vision system.

Figure 10-3. The da Vinci Si Robotic System (Intuitive Surgical, Sunnyvale, CA) with dual surgeon console. (© 2015 Intuitive Surgical, Inc. Used with permission.)

with the robotic system and used for the assistant and support staff image viewing. The newest generation of the robotic surgical system (da Vinci Si) has the capacity for a second surgeon's console to support training and collaboration.

Placement of the Operative Team for Laparoscopic Procedures

Transperitoneal Procedures in the Upper Abdomen

Laparoscopic. For transperitoneal laparoscopic renal and adrenal surgical procedures, the patient is positioned in a modified lateral decubitus position. The surgeon and assistant usually stand in front of the abdomen with the patient in the lateral decubitus position (i.e., for a left nephrectomy the surgeon and assistant stand on the right side of the operating table). The instrument table and the scrub nurse are best located on the opposite side of the patient near the foot of the bed, such that instruments can be handed to the surgeon over the table (Fig. 10-4A). Incoming lines from insufflators, suction and irrigation, electrosurgical devices, and so on enter from the contralateral side of the table or from the ipsilateral head of the table. Additional technology (e.g., laparoscopic ultrasound probe) may be moved to the operating table depending on the surgeon's needs, as well as on the availability of space.

To provide more comfortable positioning of the surgeon's arms, a 6- × 4-foot, 6-inch lift can be used when the operating table cannot be lowered sufficiently to allow the surgeon to hold the laparoscopic instruments with his or her elbows held comfortably at the side rather than extended laterally. This is most important during suturing.

Robotic. For transperitoneal robotic-assisted laparoscopic renal and adrenal surgical procedures, the patient is again positioned in a modified lateral decubitus position. The assistant usually stands in front of the abdomen with the patient in the lateral decubitus position (i.e., for a left nephrectomy the assistant stands on the right side of the operating table). The robotic arms (i.e., patient-side cart) are brought in from the opposite side (i.e., facing the back with the patient in the lateral decubitus position), such that the robotic arms stretch over the patient and can then be docked to the preplaced ports. In general, it is best to angle the robot slightly such that the

camera is pointing directly toward the site of interest. Accordingly, depending on the exact port placement, the robotic arms may be brought in at an angle toward the head of the patient, as opposed to perpendicular to the operating table, to minimize clashing of the robotic arms once docked (Fig. 10-5 on the Expert Consult website). The instrument table and the scrub nurse are best located at the foot of the bed on the same side of the patient as the surgical assistant, such that instruments can be easily handed to the surgical assistant (see Fig. 10-4B). The robotic console can be placed anywhere in the room remote from the operating table and instrument table such that it is out of the way, but in view of the patient and anesthetic monitors. All incoming lines from insufflators, suction and irrigation, and electrosurgical devices enter either from the contralateral foot side of the table or the ipsilateral head of the table.

Retroperitoneal Procedures in the Upper Abdomen

Laparoscopic. For retroperitoneal renal and adrenal procedures, the patient is placed in the true, 90-degree lateral decubitus position with the body at a right angle to the table. All of the proper steps for padding in this position should be followed (see earlier). The table is angled at the hip to accentuate and increase the distance between the 12th rib and the iliac crest. Maximizing this distance is paramount with regard to port placement. Both the primary surgeon and the camera assistant stand facing the patient's back (Fig. 10-6A). The scrub nurse or technician stands facing the patient's front, and instruments are handed across the patient accordingly.

Robotic. For retroperitoneal robotic-assisted renal and adrenal procedures, the patient is similarly placed in the true 90-degree lateral decubitus position. The surgical assistant can stand facing either the patient's abdomen or his or her back depending on the surgeon's preference for port placement. The instrument table and scrub nurse are best placed on the same side as the assistant near the foot of the table. The robotic arms are brought in over the head of the patient (Fig. 10-6B). Because the robotic arms are positioned over the patient's head, the anesthesiologist and the anesthetic cart and monitors should be positioned off to the side, in front of the patient, at the head of the bed.

Transperitoneal and Extraperitoneal Pelvic Procedures

Laparoscopic. The patient is positioned in the supine position with the legs on split-leg positioners or elevated in stirrups that have knee and leg supports to avoid perineal nerve injury. The table is angled (flexed) slightly at the hip to accentuate the pelvis. The patient's arms are tucked at the sides; plastic sleds can be used to support the arms. A slightly snug chest strap should be placed directly across the patient's chest. The table is placed in the 30-degree Trendelenburg position. The surgeon stands on the side of the table

where he or she is comfortable, and the assistant stands on the opposite side (Fig. 10-7A).

Robotic. For robotic procedures on the pelvis the patient is positioned exactly as described previously for laparoscopic pelvic procedures. After port placement the robotic arms are placed between the patient's legs, and the assistant can remain on either side of the table depending on surgeon preference (Fig. 10-7B). The scrub nurse or technician can be positioned on the same side as the assistant to facilitate passing instruments because passing instruments across the robotic arms can be cumbersome.

PERFORMING THE PROCEDURE

Before the Initial Incision

A checklist ensuring that all essential equipment is present and operational should be completed just before initiation of the pneumoperitoneum (see Box 10-1).

Additional items to check when using the da Vinci Robotic System include ensuring that all plugs for the console, vision cart, and patient-side cart are plugged into different circuits and that all cables connecting these carts are connected properly. The system should be turned on and the self-test and homing routine should be complete. The three-dimensional (3D) camera and endoscopes should be calibrated, the image black and white balanced, and target alignment performed according to the manufacturer's instructions. The patient-side cart should be draped and ready.

Achieving Transperitoneal Access and Establishing the Pneumoperitoneum

Achieving transperitoneal access is the first step before establishing a pneumoperitoneum. This can be done using either a closed (i.e., Veress needle) or open (i.e., Hasson cannula) technique.

Closed Techniques

Veress Needle. A disposable (70- or 120-mm, 14-gauge, and 2-mm outer diameter) or nondisposable Veress needle can be used. Proper needle function should be ensured before the procedure. Specifically, the blunt tip of the needle is tested to make sure it retracts easily and the needle is connected to the CO₂ line to ensure that there is no resistance to gas inflow (i.e., at 2-L/min flow, pressure remains at ≤ 2 mm). Last, saline is flushed through the needle with the tip manually occluded to make sure there is no leakage at the juncture between the shaft and the hub of the needle.

For proper placement the Veress needle is grasped at midshaft and is passed perpendicularly through skin using a gentle, steady pressure. Two points of resistance are traversed: the abdominal wall fascia and the peritoneum.

Sites for Needle Passage. With the patient in the supine position, the head of the bed is lowered 10 to 20 degrees; insertion of the Veress needle is commonly accomplished at the superior border of the umbilicus. There are certain advantages to choosing the umbilical area as the site for initial trocar placement: the abdominal wall is thinnest, and postoperative cosmesis is excellent. However, this point of entry is fraught with the potential for injury to a major vessel, in particular the left common iliac vessels, aorta, or vena cava. As such, it is important to note when considering the abdominal area as the site for Veress needle placement that body habitus influences the relative location of the umbilicus to underlying vascular structures. In obese patients, the umbilicus tends to migrate inferiorly, whereas in nonobese patients the umbilicus lies in its commonly described position, directly above the bifurcation of the aorta and vena cava. Thus, for umbilical access in nonobese patients the Veress needle should be passed through the abdominal wall angled toward the pelvis to avoid injury to the bowel and great vessels that lie directly beneath. In more obese patients, because the umbilicus lies more caudad, less angulation is needed and the Veress needle should be passed perpendicular to the umbilical incision (Loffer and Pent, 1976).

The right or left lower quadrant can also be used with the patient in the supine position, decreasing the likelihood of vascular injury. However, one must be cognizant of risk for colonic injury with this site. If the patient is in a lateral decubitus position, then the Veress needle can be passed two fingerbreadths medial and two fingerbreadths superior to the anterior superior iliac spine.

Other potential insertion sites when the patient is either supine or in a lateral decubitus position are at the Palmer point (i.e., subcostal in the midclavicular line on the left side) and at the corresponding site on the right side. The Palmer point is the preferred

site when extensive intra-abdominal adhesions are suspected (Palmer, 1974). With either of these insertion sites care must be exercised; if the needle is inserted too deeply, there is the potential to hit the liver on either side or, rarely, the spleen on the left side. Alternatively, in the abdomen that has previously been operated on, insertion should be performed in an unscarred quadrant of the abdomen. If there is no scar-free area, then an open technique (see later) should be used.

The safety of the Veress needle technique has been demonstrated in numerous studies including a study by Chung and coworkers (2003) that examined the outcome of 622 consecutive cases with Veress needle insertion. Prior abdominal surgery had been performed in 192 patients (31%), and the BMI was 30 or greater in 98 patients. Blind Veress needle placement was successful in 579 (93%), and outcome was not associated with laterality, type of surgery, or prior surgery. In 34 cases (5%), a minor laceration to the liver was managed conservatively without sequelae; and in 21 cases (3%) the omentum or falciform ligament was traversed without significant injury. No major complications, such as vascular or hollow-organ perforation, were caused by either the Veress needle or trocar. Neither the spleen nor bowel was ever injured.

Assessing Proper Needle Placement. First the aspiration-irrigation-aspiration test is performed. With the use of a 10-mL syringe containing 5 mL of saline, the Veress needle is aspirated to check for blood or bowel contents. If this test result is negative, then the saline is injected into the abdominal cavity; this should occur without any resistance. Next, the plunger of the syringe is again withdrawn; no fluid should return into the barrel of the syringe. An additional injection of 2 to 3 mL of saline will help to expel any omentum that may have been sucked into the needle tip with the original aspiration technique. Last, the syringe is detached from the Veress needle and any fluid left in the hub of the needle should fall swiftly into the peritoneal cavity (i.e., the "drop" test).

Second, the advancement test can be performed. If the needle has truly just entered the peritoneal cavity, then the surgeon ought to be able to advance the needle 1 cm deeper without the tip meeting any resistance. Resistance at this stage usually means the needle is still in the preperitoneal space and needs to be advanced through the remaining peritoneum.

Insufflation should never be initiated unless all the signs for proper peritoneal entry (negative aspiration, easy irrigation of saline, negative aspiration of saline, positive drop test, and normal advancement test) have been confirmed. Once proper needle placement is verified, insufflation is started at 2 L/min with the abdominal pressure set at 10 mm Hg. If free flow of CO₂ is noted (i.e., intra-abdominal pressure remains <10 mm Hg), then after 0.5 L has entered the abdomen the flow can be increased to maximal capacity of 9 L/min (however, no more than 2 L/min flow can be achieved through a 14-gauge needle) and the abdominal pressure set at 15 mm Hg. As soon as the preset limit of 15 mm Hg of intra-abdominal pressure is reached, free flow stops.

Stabilization of the abdominal wall fascia with towel clips or Allis clamps at the time of Veress needle puncture may help in stabilizing the fascia; however, one should not lift up on the fascia because this will only increase the space between the fascia and the peritoneum while not changing the intra-abdominal space.

EndoTIP Entry. See the Expert Consult website for details.

Open Access Techniques

Hasson Technique. The pneumoperitoneum can be more easily, and in one's early experience, more safely established using the open Hasson technique; however, its use involves making a larger incision and increases the chances of port-site gas leakage during the procedure. The open technique is recommended specifically when extensive adhesions are anticipated. Studies in general surgery have shown the open technique to be as efficient as the closed approach and slightly more or equally safe (Bonjer et al, 1997).

In the unscarred abdomen, with the patient in the supine position, a 2-cm semicircular incision is made at the lower edge or

A 5- or 10-mm incision is made in the skin at an appropriate site for a 5- or 10-mm port. The EndoTIP trocar (Karl Storz, Tuttlingen, Germany) is a trocar with a “corkscrew”-type self-advancing and self-retaining entry system and a blunt tip (Fig. 10-8). The trocar can be advanced through the abdominal wall while a 0-degree lens is positioned inside the trocar 1 cm from the advancing tip. Once the abdominal wall muscle is engaged, the EndoTIP can be lifted up slightly while continuing to rotate it through the tissues; this maneuver lifts the peritoneum, and one can watch as the blunt tip works its way through the peritoneum and into the abdominal cavity. Again, this technique should be used only in patients in whom intra-abdominal adhesions are unlikely.

Figure 10-8. The EndoTIP trocar (Karl Storz, Tuttlingen, Germany).

Figure 10-9. Various reusable Hasson type trocars.

slightly below the umbilicus. The fascia and peritoneum are opened individually with a transverse incision, sufficient to accommodate the surgeon's index finger. After visual and digital confirmation of entry into the peritoneal cavity, two 0 silk traction sutures are placed on either edge of the fascia. Next, the Hasson cannula is advanced through the incision with the blunt tip protruding (Fig. 10-9). The funnel-shaped adapter of the Hasson cannula is advanced until it rests firmly in the incision, and it is then tightened onto the cannula with the attached screw; fixation to the abdominal wall is provided with the fascial sutures that are wrapped around the struts on the funnel-shaped adapter of the Hasson cannula, thereby anchoring it in place. After removal of the obturator, free flow of CO₂ into the peritoneal cavity is achieved by attaching the CO₂ tubing to the cannula. The insufflator can be set at maximum inflow, thereby creating the pneumoperitoneum quickly.

A far simpler type of blunt cannula is a balloon retention device (e.g., Blunt Tip Trocar with Balloon Tip, US Surgical, Norwalk, CT or the Kii Balloon Blunt Tip System, Applied Medical Resources, Rancho Santa Margarita, CA) (Fig. 10-10 on the Expert Consult website). Once the cannula is positioned in the abdominal cavity, the balloon is inflated; the cannula is pulled upward until the balloon is snug on the underside of the abdominal wall. Next, the soft foam or rubber collar on the outside surface of the cannula is slid down until it is snug on the skin and locked in place. This process creates an excellent seal, precluding gas leakage and subcutaneous emphysema.

Hand Port Access. The pneumoperitoneum can be obtained before or after making the hand port incision. If the surgeon has little experience with achieving a pneumoperitoneum, the safest maneuver is to use an open technique and place the hand port into a 6.5- to 7.5-cm open incision and then create the pneumoperitoneum through the hand port (i.e., hand port access). For this technique, the procedure begins with making a standard midline or lower quadrant incision at the planned hand-assist site. The peritoneal cavity is entered in the standard open surgical fashion, after

which the hand-assist device is placed according to the manufacturer's instructions. Next, a blunt cannula is passed through the hand-assist device and a pneumoperitoneum is established. Additional 5-mm or 10- to 12-mm ports can be placed rapidly under manual control with the surgeon's intra-abdominal hand being used to guide the additional trocars through the abdominal wall. Alternatively, a laparoscope can be placed through the port placed in the hand-assist device for insufflation, and the rest of the trocars can then be placed under direct vision.

Technique for Laparoendoscopic Single-Site Surgery

See the Expert Consult website for details.

Achieving Retroperitoneal Access and Developing the Retroperitoneal Space

Technique for Balloon or Self-Styled Dilator Placement: Open (Hasson) Technique

The Hasson technique is the most commonly used technique because it affords the greatest precision during development of the retroperitoneal space (Gill, 1998). Initial access is obtained through a 2.0- to 2.5-cm transverse incision in the midaxillary line, just below the tip of 12th rib. The wound is opened with a pair of S-retractors. Under direct vision, the posterior layer of the lumbar fascia is incised and muscle fibers are split or divided. The retroperitoneal space is entered, **under direct vision**, by making a small incision in the anterior thoracolumbar fascia with an electrocautery blade or, less commonly, by bluntly piercing the fascia digitally or with a hemostat. Care should be taken that this fascial opening is snug around the index finger and no larger, so that intraoperative air leak is minimized. Index finger palpation of the belly of the psoas muscle posteriorly and the Gerota fascia-covered inferior pole of the kidney anteriorly confirms proper entry into the retroperitoneal space (Fig. 10-11A). The index finger is used to digitally create a space in this precise location for placement of the balloon dilator; two inflations of the balloon are then done—one directed cephalad and the second directed caudad to fully dilate the retroperitoneal space (Fig. 10-11B). Thus, balloon dilation is performed anterior to the psoas muscle and fascia and outside and posterior to the Gerota fascia. In cases involving definitive ureteric mobilization (e.g., retroperitoneoscopic donor nephrectomy, nephroureterectomy), additional balloon dilation may be performed more caudad to the primary site of dilation (Gill et al, 1995). Similarly, during a retroperitoneoscopic adrenalectomy, it is helpful after the initial balloon dilation to move the balloon up higher in the retroperitoneum and perform a second, even more cephalic balloon dilation along the undersurface of the diaphragm (Sung and Gill, 2000).

Balloon Dilation. Gradual distention of a balloon dilator in the retroperitoneal space atraumatically displaces the mobile fat and moves the peritoneum forward relative to the immobile body musculature. This device thus creates a working space equivalent to the size of the balloon. Either commercially available balloon dilators (Fig. 10-12) or a self-styled dilator can be used.

See the Expert Consult website for details on commercially available balloons and self-styled dilators.

Manual Dilation. See the Expert Consult website for details.

Achieving Extraperitoneal Access and Developing the Extraperitoneal Space

Technique for Balloon or Self-Styled Dilator Placement: Open (Hasson) Technique

A 1.5- to 2-cm curvilinear incision is made along the inferior umbilical crease. The anterior rectus sheath is incised vertically for 1.5 cm, and the rectus muscle is separated in the midline to expose the

Figure 10-10. Blunt-tipped trocar with balloon tip.

Recent advances in abdominal access technology combined with the development of curved and articulating laparoscopic instrumentation have made it possible to perform selected procedures through a single incision (typically a 2.5-cm transumbilical incision); using three access ports through this incision, the laparoscope and two working instruments can be introduced.

Much the same as for hand port access, the incision can be made before or after obtaining a pneumoperitoneum depending on surgeon preference. Typically, the incision is made periumbilically for cosmetic purposes. The size of the skin incision should correspond to the surgical task at hand. If the procedure does not require removal of a large intact specimen, then the incision should be minimized to as little as 2.5 cm. If the procedure requires large intact specimen removal (as in donor nephrectomy), then the incision should be large enough to extract the specimen.

Once the incision has been made, several ports side by side or a single triport access device (see later) can be placed and a pneumoperitoneum is reestablished at high flow.

Thus far, laparoendoscopic single-site surgery (LESS) has been used for a variety of upper abdominal procedures including adrenalectomy (Hirano et al, 2005; Castellucci et al, 2008); renal biopsy (Kaouk et al, 2008b); renal cyst decortication; renal tumor cryoablation (Goel and Kaouk, 2008); pyeloplasty (Kaouk et al, 2008a); ileal ureter interposition; psoas hitch ureteroneocystostomy; simple,

radical, and donor nephrectomy (Gill et al, 2008; Ponsky et al, 2008b; Raman et al, 2008; Rane and Rao, 2008); and partial nephrectomy (Kaouk et al, 2008b). In addition, pelvic procedures have been performed including varicocelectomy (Kaouk and Palmer, 2008), sacrocolpopexy (Kaouk et al, 2008b), radical prostatectomy, and radical cystectomy with extended lymphadenectomy (Kaouk et al, 2008b).

The theoretic advantages of LESS over standard multi-incision laparoscopy are improved cosmesis, decreased pain, and faster recovery time. At the present time, however, there are insufficient data regarding LESS to either support or refute these potential benefits (Raman et al, 2008; Merseburger et al, 2013). Considering the technically demanding character of the single-site approach, only experienced laparoscopic surgeons should attempt this technique in clinical settings. Research in this area is ongoing, and until well-established methods and results are available, surgeons are urged to approach LESS in a responsible and graduated fashion. One method of transitioning from standard laparoscopy to LESS for selected procedures is to gradually decrease the number of ports one uses until the procedure can be performed through a single incision. Conversely, when one is having difficulty performing a procedure using LESS, the surgeon should not hesitate to place one or more extra trocars at separate incision sites to improve triangulation and thereby ensure safety and a high-quality result.

Commercially Available Balloons. Commercially available trocar-mounted preperitoneal balloon dissectors (PDBs) (e.g., Covidien Ltd., Mansfield, MA) are typically a transparent, high-tensile strength silicone balloon that is inflated with a sphygmomanometer bulb insufflator using room air (see Fig. 10-12). The balloon has a maximum capacity of 800 mL (40 pumps of the inflating bulb). A primary advantage of commercially available balloons is that the balloon is affixed to the end of a stiff, hollow, transparent plastic shaft. This shaft allows precisely directed placement of the balloon dilator. Furthermore, because the laparoscope can actually be inserted into the shaft of the balloon dilator during the inflation process, it provides the capability for endoscopic confirmation of the proper positioning of the transparent balloon and of the adequacy of the controlled radial dilation of the extraperitoneal area. Balloon dilators are commercially available in two different shapes: a round balloon for dilation of the pelvic extraperitoneal space and a horizontally oriented, oblong balloon for dilation of the retroperitoneal space.

Self-Styled Dilators. Gaur's original (1992) version of the balloon dilator was a size 7 surgeon's glove mounted on a No. 8 red rubber catheter. The external end of the catheter was connected to a sphygmomanometer bulb insufflator, and the balloon was insufflated to 110 mm Hg. After this initial description, several other self-styled dilators were described: the middle finger of a size 7 to 8 glove, two fingers of a size 7 to 8 glove tied over each other for additional strength, a sterile condom, and the cot of an O'Connor-style drape mounted on a 16- or 18-Fr red rubber or whistle-tip catheter (Webb

et al, 1993; Chiu et al, 1995). For the balloons made from the middle finger of a surgeon's glove, the finger is affixed to the rubber catheter with two 0 silk sutures. These self-styled dilators were filled with saline rather than air. The device may be back-loaded into a well-lubricated (i.e., K-Y jelly) 30-Fr Amplatz sheath to facilitate introduction through a laparoscopic port. Although it is economically advantageous, drawbacks of the self-styled balloon include the lack of a stiff shaft to manually direct the balloon into a specific location for precise dilation, and the inability to endoscopically monitor the dilation process from within the balloon.

An ex vivo laboratory study demonstrated that increasing volumes of saline induced gradual pressure increments within the middle finger of a surgeon's glove. At a volume of 1000 mL, the average pressure was 15 mm Hg. Pressures remained 15 mm Hg at 1500 mL and increased to 17 mm Hg at 2000 mL (McDougall et al, 1994). In practice there is no need to exceed the 1000-mL limit. Also, latex balloons have less tensile strength than silicone balloons, making them more likely to rupture. Regardless, with either balloon setup, on the few occasions that either type of balloon has ruptured there has been no obvious complication. However, the latex balloon has a tendency to rupture into multiple pieces whereas the Silastic balloon usually leaves only one large fragment, making retrieval an easier task.

Complications associated with balloon dilation stem from improper balloon placement or balloon rupture. Intramuscular dilation may result in hernia formation, or inadvertent peritoneal disruptions may occur (Gaur, 1992; Adams et al, 1996).

Creation of a working space within the retroperitoneum may also be achieved exclusively with a combination of digital and laparoscopic instrument dissection ([Kerbl et al, 1993](#)). After access to the extraperitoneal area is gained, to-and-fro movements of the laparoscope are performed to create a working space ([McKernan, 1995](#)). This technique has been used to perform various simple and advanced procedures in the retroperitoneum ([Rassweiler et al, 1998a](#); [Abbou et al, 1999](#)). Although it is effective, potential disadvantages of this technique include frequent cleaning of the laparoscope and the lack of clear landmarks initially due to the smaller, undeveloped working space.

Figure 10-11. A, Access into the right retroperitoneum. Through the primary port incision at the tip of the lowest (12th) rib, open access is gained into the retroperitoneum after piercing the thoracolumbar fascia. Finger dissection is performed anterior to the psoas muscle and fascia to create a space for insertion of the balloon dilator. Confirmation that the finger dissection is indeed being performed in the proper plane is obtained by palpating the psoas and erector spinae muscles between the retroperitoneally located index finger and the fingertips of the opposite hand positioned on the patient's back. The fat-covered lower pole of the kidney can be palpated in a cephalad direction by turning the finger clockwise in the retroperitoneum on the right side. B, Balloon dilation in the posterior pararenal space facilitates the creation of a working space for retroperitoneal laparoscopic nephrectomy (*coronal view*).

Figure 10-12. Example of a commercially available balloon dilator for creating space in the retroperitoneum: preperitoneal balloon dissector. (Courtesy Covidien Ltd., Mansfield, MA.)

posterior rectus sheath. With the surgeon's index finger positioned posterior to the rectus muscle and anterior to the posterior rectus sheath, gentle tunneling motions are made in a caudal direction until the area of the symphysis pubis is reached. At this distal location, the fascia transversalis is punctured with the fingertip, and gentle side-to-side digital dissection is performed in the prevesical space, posterior to the pubic bone. Into this predeveloped space, a balloon dilator or self-styled dilator (see earlier) is inserted and distended to create an adequate working space. Balloon dilation or self-styled dilation effectively displaces the prevesical fat and reflects the peritoneum cephalad. The balloon is initially inflated in the midline and then reinflated on either side to further expand the working area (Meraney and Gill, 2001).

Caveat: In earlier studies of retroperitoneoscopy, excessive subcutaneous emphysema and higher carbon dioxide levels were the norm owing to use of the standard Hasson cannula (Wolf et al, 1995; Ng et al, 1999); this situation was rectified with the introduction of the open access blunt balloon port, which has a balloon to secure it against the underside of the abdominal wall and a soft foam cuff to secure it to the outer abdominal wall, creating an airtight seal (Ng et al, 1999).

Limitations and Advantages of Transperitoneal versus Extraperitoneal Approach to the Flank and Pelvis

See the Expert Consult website for details.

Access Technology: Trocars, Hand Ports, and Single-Port Access

Trocars

Trocars enable the laparoscopist to introduce working instruments into the gas-filled abdomen or retroperitoneum. They also maintain the pneumoperitoneum by conveying the insufflant and may serve as pathways for delivering small amounts of dissected tissue from the surgical area. Typically a trocar consists of an outer hollow sheath (also called a *cannula* or *port*) and an inner obturator, which is removed as soon as the outer sheath has entered the peritoneal cavity.

A variety of nondisposable and disposable trocars are available (Fig. 10-13). Standard models range from 3 to 20 mm in diameter and 5 to 20 cm in length. One-way valves within the trocar allow the surgeon to exchange instruments through the port without the escape of significant amounts of gas. Some older trocar models have trapdoor or flap valves. In such trocars it is necessary to depress the valve lever to open the valve widely during retrieval of tissue or needles. More recently, **multiseal**-type valves have become available for 10- and 12-mm trocars that accommodate the passage of 5-mm and larger instruments without any air leak occurring; if large amounts of tissue are to be withdrawn, removal of the outer seal or of the entire valve is necessary for this procedure. The outer seal and valve can then be replaced before reinsertion of instruments.

Initially, only sharp-tipped or bladed trocars were available. On these trocars the sharp obturator incised the various layers of tissue as it entered the peritoneal cavity. To protect the underlying viscera from the sharp tip of these trocars, a plastic safety shield was later incorporated into the disposable trocars that would spring forward to shield the blade once the trocar entered the gas-filled abdomen. However, bladed trocars should be only of historical interest because they have been superseded by safer noncutting dilating trocars (i.e., blunt), which no longer require a safety shield. These trocars enter the abdomen by spreading the abdominal wall musculature, rather than cutting it. Therefore there is less chance of injuring an abdominal wall vessel, and the resulting entry site is less prone to subsequent herniation. Indeed, studies have shown the

Transperitoneal versus Retroperitoneal Renal and Adrenal Surgery. The transperitoneal and retroperitoneal approaches to the upper abdomen each offer advantages and disadvantages. Retroperitoneoscopy is associated with unique anatomic orientation with limited anatomic landmarks, save the psoas muscle. In comparison, the transperitoneal approach offers a very familiar anatomic approach with a number of landmarks (e.g., liver, spleen, large bowel). Retroperitoneal laparoscopy is also associated with a relatively restricted working space compared with transperitoneal laparoscopy. This results in a steeper learning curve with the retroperitoneal approach. Moreover, the fact that a comparatively limited space is available necessitates precise accuracy regarding the strategic placement of ports.

The degree of technical difficulty of the retroperitoneal approach increases in the presence of large specimens, including entrapment of these larger specimens, which may be very difficult. The latter problem of entrapment can be overcome by laparoscopically creating an intentional peritoneotomy at the end of the procedure to allow entrapment of the specimen within the larger peritoneal cavity.

Laparoscopic reconstruction and intracorporeal suturing are technically demanding procedures regardless of the approach. However, in the retroperitoneal space, reconstruction can be more challenging compared with transperitoneal laparoscopy owing to suboptimal instrument angulation and a smaller working space. One potential way to overcome some of these limitations is to use a robotic approach to the retroperitoneum. [Kaouk and coworkers \(2008c\)](#) reported the Cleveland Clinic experience using a robotic retroperitoneal approach to perform dismembered pyeloplasty in 10 patients. They noted that the enhanced dexterity of the robotic platform did facilitate reconstructive suturing in a smaller working space.

Offsetting the limitations of retroperitoneoscopy are some distinct advantages. First, the risks of inadvertent bowel injury and postoperative ileus are minimized, although not eliminated ([Kavoussi et al, 1993](#)). This results in a slightly more rapid postoperative recovery compared with the transperitoneal approach. During retroperitoneoscopy and extraperitoneoscopy the bowel can be effectively and safely retracted within its peritoneal cover. Although out of sight, the bowel should never be out of mind, because bowel injuries can still occur.

Transperitoneal laparoscopy may be associated with an increased incidence of postoperative shoulder-tip pain, a feature rarely associated with retroperitoneoscopy. In addition, **extraperitoneoscopy and retroperitoneoscopy are associated with a significantly lower incidence of postoperative trocar site hernias.**

Another significant benefit of the retroperitoneal approach is the rapid and direct access to the renal hilum, with the renal artery being the first hilar structure encountered and controlled. Furthermore, if a partial nephrectomy is planned, it may be more effective to approach a posterior tumor from the retroperitoneal approach, whereas anterior tumors are often more easily approached from the transperitoneal approach.

Contrary to common conception, the occurrence of an inadvertent peritoneotomy during retroperitoneoscopy does not usually interfere with the subsequent steps of the procedure, and conversion to a transperitoneal laparoscopic technique is not mandatory ([Gill et al, 2000](#)).

Although a retroperitoneal approach might not be advantageous for every surgery, there are certain instances in which this approach might be more appropriate, as in the case of multiple prior transabdominal surgeries. Conversely, a history of prior retroperitoneal surgery increases the difficulty of re-entering the retroperitoneal space and therefore should be approached with caution. Subsequent attempts at extraperitoneoscopy or retroperitoneoscopy should be ventured only by individuals with considerable experience and comfort with this approach. In our experience, prior percutaneous renal procedures do not necessarily constitute a contraindication to subsequent retroperitoneoscopy, provided that entry is away from the area of the prior nephrostomy tube placement.

Transperitoneal versus Extraperitoneal Pelvic Surgery. As with the upper abdomen, the transperitoneal and extraperitoneal approaches to the pelvis both offer distinct advantages and disadvantages. The transperitoneal approach to the pelvis offers easy access to all areas of the pelvic cavity once the space of Retzius, iliac and obturator fossa, or the rectovesical space has been entered directly through the peritoneum. The working space is maximized because the peritoneum does not limit camera or instrument motion. However, potential limitations associated with this approach as compared with the extraperitoneal approach include the possibility of causing mechanical or thermal injury to the bowel and the necessity to use more extreme Trendelenburg positioning or additional retraction of the bowel to prevent it from impinging on the operative field. The possibility of prolonged ileus has also been suggested; however, in a large prospective study comparing 165 transperitoneal versus 165 extraperitoneal laparoscopic radical prostatectomy patients, [Ruiz and colleagues \(2004\)](#) did not find significant differences between the two groups in terms of hospital stay or medical and surgical complications. Operative time was half an hour shorter in the extraperitoneal group (220.0 vs. 248.5 minutes, $P < .0001$). These findings were reinforced in two other studies comparing the two approaches. In these two studies, patients undergoing radical prostatectomy via the two approaches were matched with regard to important preoperative attributes and the outcomes compared. The authors found no significant differences between the extraperitoneal and transperitoneal approaches regarding all important parameters, except that the operative time for the extraperitoneal approach was in general a little shorter (30 minutes) ([Erdogru et al, 2004](#); [Madi et al, 2007](#)).

One undeniable advantage of the extraperitoneal approach is that it avoids the necessity of lysis of adhesions in patients who have had prior abdominal surgery. In contrast, for patients who have had prior laparoscopic inguinal hernia repair, a transperitoneal approach is more advantageous.

Unlike with retroperitoneoscopy, the occurrence of a peritoneotomy during extraperitoneoscopy may interfere with the performance of subsequent extraperitoneal dissection, and conversion to a transperitoneal technique may be required ([Meraney and Gill, 2001](#)).

In summary, for most cases there does not seem to be a clear advantage to use of a transperitoneal versus extraperitoneal approach for laparoscopic and robotic pelvic surgery. In selected cases described earlier there may be advantages of one approach over the other.

Figure 10-13. Various trocar designs showing (left to right) reusable blunt-tipped, reusable bladed, and two disposable visual obturator fascial dilating designs.

risk of inferior epigastric injury or port site herniation is fivefold less with blunt versus sharp trocars (Hashizume and Sugimachi, 1997; Thomas et al, 2003). In addition, a recent meta-analysis demonstrated a lower relative risk of trocar site bleeding (3% vs. 9%) and overall complications (3% vs. 10%) with blunt compared with bladed trocars (Antoniou et al, 2013).

As with the older sharp trocars, there are both disposable and nondisposable blunt trocar units. One form of blunt disposable trocar unit is the Step needle and sleeve (Covidien). This disposable system uses a needle port with an outer diameter of 2.1 mm (6.5 Fr) that incorporates a Veress needle introducer (Fig. 10-14 on the Expert Consult website). After correct and successful puncture of the abdomen and establishment of the pneumoperitoneum, the Veress needle introducer is removed and the remaining sheath is an expandable port that can then be expanded by passage of a blunt-tipped obturator to expand the collapsed sheath to 5 mm, 10 mm, or 12 mm, depending on the surgeon's needs.

Other blunt-tipped trocars are produced by all of the major trocar manufacturers. These devices have a variety of tips that enable their placement by spreading the tissues; some also have a clear plastic tip (i.e., optical trocar) such that the surgeon can pass an endoscope into the trocar to endoscopically monitor its passage through the abdominal wall and its entry into the gas-filled abdomen.

A unique reusable blunt-tipped port, the EndoTIP system (Karl Storz), is a screwlike device that has no sharp points or cutting edges (see Fig. 10-8). It comes in 5-, 10-, and 12-mm designs; however, the 10- and 12-mm trocars require use of a cumbersome reducer system because they are not a multiseal design (see earlier). Unlike the action of trocars with a sharp tip, the tissue is not cut but is only displaced and bluntly dilated, thereby preserving the closing mechanism of the overlying muscle and fascia. Because of its innovative design, this device reduces injury to the intra-abdominal organs, stays securely in place, and seals the point of entry against any inadvertent loss of gas.

For the da Vinci Robotic System the camera lens fits through a variety of standard 12-mm disposable trocars. The 8- and 5-mm instruments fit through proprietary reusable 8- and 5-mm trocars that couple directly with the robotic arms. These reusable metal trocars have disposable valves that must be changed with each new case and the option of a reusable blunt inner cannula or a bladeless disposable inner cannula for use during placement.

In traditional flap-valve or trap door ports, a reducer is necessary to allow downsizing of working channels in 10-mm or larger trocars to accommodate smaller, 5-mm working instruments without any leakage of CO₂. However, the development of multiseal technology and the even newer AirSeal technology (discussed later), has resulted in valves that can accommodate 5- to 12-mm instruments without the need for a reducer, which can save significant time during a long procedure.

Retention of the cannula at the port site is essential to decrease air leak and subcutaneous emphysema and facilitate the timely completion of a procedure. In the past it was necessary to affix a suture to the insufflation side port and the skin to secure the trocar. At present, myriad retention mechanisms exist to prevent dislocation of cannulae such as threaded sleeves, adjustable threaded sleeves, expandable arms, and inflatable balloons. The Blunt Tip Trocar with Balloon Tip (US Surgical) and the Kii Balloon Blunt Tip System (Applied Medical Resources) (see Fig. 10-10 on the Expert Consult website) have a retention balloon that can be inflated in the peritoneal cavity and then drawn up tightly against the peritoneal side of the abdominal wall; an outer foam or rubber sealing ring can then be advanced down the extra-abdominal shaft of the cannula, thereby sandwiching the abdominal wall between the inflated balloon and the foam or rubber seal, effectively precluding any leakage of gas during the case. Use of this device minimizes CO₂ leakage around the primary port incision, thus reducing the incidence of subcutaneous emphysema and hypercarbia. This is especially effective when doing retroperitoneoscopic procedures. Another self-sealing trocar, the AnchorPort (SurgiQuest, Milford, CT) has an elastic self-sealing trocar shaft that automatically forms to the patient's body wall when the inner cannula is removed, creating a tight seal.

A recent technologic advance in trocar and insufflation technology has addressed some of the limitations of existing trocar systems including air leak, need for reducers, and specimen removal. This new system, the AirSeal System (SurgiQuest), consists of a specialized Intelligent Flow System insufflator (Fig. 10-15A on the Expert Consult website) featuring a circulatory flow design, a valve-free Access Port (Fig. 10-15B and C on the Expert Consult website), and a Tri-Lumen Filtered tube set (Fig. 10-15D on the Expert Consult website). This system has the ability to provide a stable pneumoperitoneum despite continuous high-flow suction, trocar dislodgement, or excessive port-side leakage. The valve-free design of the Access Port allows smudge-free scope insertion, intact specimen removal, and easy insertion and withdrawal of instruments of varying sizes. The AirSeal System also provides continuous smoke evacuation without the fear of venting surgical smoke and plume into the operating room.

Hand-Assist Devices

A number of hand-assist devices exist, including the GelPort (Applied Medical Resources), the Omniport (Advanced Surgical Concepts, Wicklow, Ireland), and the Lap Disc (Ethicon, Cincinnati, OH).

A study of 130 urologists participating in a series of hand-assist courses evaluated these three different hand-assist devices for a variety of features. The GelPort device emerged with the highest overall score, followed by the Lap Disc and then the Omniport (Patel and Stifelman, 2004). Advantages of the GelPort included sturdiness, ease of hand exchange, maintenance of the pneumoperitoneum, and the ability to pass both a hand and a laparoscopic instrument simultaneously.

An important caveat with respect to using hand-assist devices is the impact on the surgeon. Studies have shown that compared with standard laparoscopy, pain and numbness of the surgeon's hand, wrist, and forearm and, to a lesser extent, overall fatigue are much greater with use of a hand-assist device (Monga et al, 2004; Gofrit et al, 2008).

See the Expert Consult website for details of the hand-assist devices.

Laparoendoscopic Single-Site Surgery Access Devices

See the Expert Consult website for details.

Trocar Placement

Placement of Initial Trocar

When the Veress needle technique is used, after establishment of the pneumoperitoneum an incision is made for placement of the

Figure 10-14. Step needle and sleeve disposable trocar system. (Courtesy Covidien Ltd., Mansfield, MA. All rights reserved. Used with permission of Covidien.)

Figure 10-16. Hand port devices. A, GelPort. B, Lap Disc. C, Omniport. (Courtesy SurgiQuest, Milford, CT.)

The GelPort (Fig. 10-16A) consists of a gel-like disc that easily admits the surgeon's hand and then molds around the wrist and arm. The latest GelPort design has a 12-cm footprint. The GelPort offers the advantages of never losing a pneumoperitoneum on hand exchange because it immediately seals after hand removal, and it does not require adjustment to maintain a seal. Additional instruments can be passed alongside the surgeon's hand, through the gel material, also without loss of the pneumoperitoneum.

The Lap Disc (Fig. 10-16B) is a one-piece unit that has an inner diaphragm that is used to anchor it across the abdominal wall and an outer appliance that dials down a thin plastic sheet, like a camera

iris, around the surgeon's wrist. Although this device has a low profile and small footprint (12 cm), it does result in loss of the pneumoperitoneum every time the hand is removed and reinserted, and instruments cannot be passed parallel to the surgeon's hand.

The Omniport (Fig. 10-16C) is a balloon-like device that anchors itself as one piece across the abdominal wall. The inflated device also creates a seal between itself and the surgeon's wrist. The device has a small footprint (12 cm); however, it must be uninflated and reinflated each time a hand is exchanged, which results in loss of the pneumoperitoneum. Furthermore, no additional devices can be passed parallel to the surgeon's hand through the device.

Figure 10-17. Commercially available ports for laparoendoscopic single-site surgery. A, TriPort. B, SILS Port.

Figure 10-18. Single-site platform for the da Vinci Si System. A, Schematic diagram of access port with curved trocars. B, Robotic arms docked to single-site platform. C, Curved robotic instruments within trocars with camera. (© 2015 Intuitive Surgical, Inc. Used with permission.)

There are two basic methods used to perform LESS. One technique is to make a 2.5-cm incision, typically periumbilical or transumbilical (although an alternate site may be necessary), through which a skin flap can be raised off the abdominal wall fascia. Then, through this single incision, several (two to four) standard 5-mm laparoscopic ports can be placed in close proximity to one another. A laparoscope and working instruments can then be placed through these ports. This is obviously the most cost effective technique.

Alternatively, a commercially available single-site surgery device can be used. These devices currently require a single incision that is typically placed periumbilically or transumbilically unless the procedure dictates an alternate site. Currently there are three devices that are available for commercial use: the TriPort (Advanced Surgical Concepts), the Uni-X (Pnavel Systems, Cleveland, OH), and the SILS Port (Covidien).

The TriPort is a two-piece system consisting of an inner diaphragm that works like a wound protector and an outer piece containing the ports (Fig. 10-17A). The wound protector component is adjustable and cinches down the outer attachment, creating a tight seal on the abdominal wall. The TriPort, which requires a

12- to 25-mm incision, has room for a 5-mm laparoscope and two 5-mm working instruments plus a separate insufflation valve. The same manufacturer also makes a four-port model called the QuadPort that contains two 12-mm and two 5-mm instrument insertion sites; it requires a 2.5- to 6.5-cm incision.

The Uni-X is a similar device that is anchored to the abdominal wall by preplaced facial sutures. It has three 5-mm insertion sites and can be placed through a 1.5-cm incision (Kaouk et al, 2008b).

The third available device is the SILS Port, which can be placed into a 2-cm incision and can house three 5-mm ports or two 5-mm ports and a 5- to 10-mm port (see Fig. 10-17B).

Robotic Considerations. Intuitive Surgical has recently developed a single-site platform for the da Vinci Si System. The da Vinci single-site port is a five-lumen port that provides access for two single-site instruments, the 8.5-mm endoscope, a 5- or 10-mm accessory port, and an insufflation adaptor (Fig. 10-18A and B). The port has a pliable architecture that enables simple and safe entry into a 2.0- to 2.5-cm incision. Curved 5-mm instrument cannulae and trocars have been designed for specific use with the single-site port and are meant to optimize triangulation toward the target anatomy and provide an unobstructed view of the surgical field (Fig. 10-18C).

initial trocar. Alternatively, if an incision was made for placement of the Veress needle, the edges of the wound and subcutaneous tissue are spread with blunt forceps. Next, the trocar is held in the dominant hand with the middle finger extending along the shaft and the trocar is inserted using a twisting downward motion. The nondominant hand can be placed at the level of the skin, gently holding the trocar to stabilize it and prevent a sudden advancement. If the surgical site is in the mid to upper abdomen, then the trocar is passed perpendicular to the umbilical incision; however, for pelvic procedures, the trocar is directed 70 degrees caudad. Proof of entering the gas-filled intraperitoneal cavity is the sound of CO₂ escaping from the open sidearm. After the sidearm is closed, the obturator is removed and the CO₂ insufflation line is connected to the side port of the trocar. Alternatively, if a clear blunt port (i.e., optical trocar) is used, a 0-degree laparoscopic lens is placed within the port so the entire entry of the trocar is endoscopically monitored.

Some advocate for increasing the pneumoperitoneum after achieving access with the Veress needle in preparation for initial trocar placement to decrease the risk of underlying vascular or visceral injury with trocar insertion (Vilos et al, 2007). It is recommended to increase the pressure to 20 mm Hg. However, some data exist that suggest this may not increase the volume of the pneumoperitoneum or ease of trocar insertion (McDougall et al, 1994).

When an **open technique** is performed to obtain the pneumoperitoneum, the Hasson-style cannula used to obtain access to the abdomen also serves as the initial trocar.

Hand-Assist Placement

The hand-assist device can be placed either as an initial “port,” described earlier, or as a secondary port depending on the surgeon’s preference. When placed as a secondary port, a Veress or Hasson pneumoperitoneum is initially established and the hand-assist device is then placed under endoscopic monitoring. Establishing the pneumoperitoneum before hand port placement can help to minimize the size of skin incision for the hand port, as the skin is on stretch. The surgeon should carefully plan out the hand port entry site as well as the additional instrument and camera port sites. Every hand port device has a “footprint” that can be drawn on the abdominal wall; that footprint varies depending on the diameter of the external appliance. Care should be taken to plan out the additional trocar sites carefully to avoid interference between the hand port and the instrument ports; this is most easily done once the pneumoperitoneum has been established. After the footprint has been traced, the hand port incision site is marked; the length of the incision should correspond to the surgeon’s glove size (e.g., 7 glove size = 7-cm incision). The skin is incised, and the fascia is divided. The peritoneum is entered, and the insufflation is temporarily stopped. The hand port device is then placed according to the manufacturer’s instructions.

Before initiating a hand-assist procedure, the surgeon is advised to wrap the arm-glove seam on the hand that is to be used through the hand port either with a 1010 drape or an Ioban (3M, St. Paul, MN) “sticky drape” to waterproof his or her arm. **Lastly, the use of a brown glove on the intra-abdominal hand is recommended because they do not reflect the light from the laparoscope and thus reduce glare (Wolf, 2005).**

Secondary Trocar Placement

After obtaining access, the first step before secondary trocar placement is to inspect the entire abdomen systematically to rule out any injury to the underlying viscera that may have occurred during access or placement of the initial trocar. After this, one can proceed with secondary port placement.

Number, size, and exact location of secondary trocars depend largely on the intended laparoscopic procedure. Their configuration should be planned so that neither the tips nor handles of the cannulas cross or come into close contact with one another (a problem termed *crossing swords* and *rollover*, respectively) such that adequate working space is provided for all instruments to be used during a

particular procedure and allowing for effective triangulation at the surgical site by the endoscope and two working ports. In general, it is reasonable to place the ports in a four-point diamond pattern such that the site of the operation is encircled within the diamond. **This is particularly important when considering reconstructive renal procedures, because the angle between the horizontal plane and the needle drivers should be less than 55 degrees, whereas the angle between the surgeon’s suturing instruments should be in the 25- to 45-degree range (Rassweiler and Frede, 2002).**

It is also important to place each port so that it is pointing toward the surgical field, to avoid continued forceful redirection of the port during the procedure that may result in widening of the tissue tract around the port and development of subcutaneous emphysema.

Standard Approach. Secondary trocars are placed under direct optical control. The 30-degree lens is ideal for this portion of the procedure because turning the lens 180 degrees away from the surgical site provides the surgeon with a panoramic view of the anterior abdominal wall. The operative lights are dimmed, and the tip of the laparoscope is moved upward toward the intended site of port placement, thereby, in the thin patient, transilluminating any superficial blood vessels that need to be avoided while passing the trocar. With a blade, a skin incision is made just wide enough to accept the selected cannula. When placing secondary ports, it is of great importance to direct them toward the intended surgical field to provide tension-free maneuverability of the laparoscopic instruments. This is especially important in obese patients because the errant port will provide resistance to the surgeon throughout the rest of the procedure. Similar to placement of the initial port, all secondary ports are advanced through the abdominal wall using a slow, twisting motion and constant pressure. Each secondary port is passed into the peritoneal cavity under meticulous endoscopic monitoring. To prevent dislocation, ports that do not possess self-retaining mechanisms may be anchored to the skin using No. 2 nonabsorbable sutures. **In this regard, one should never use a metal trocar in conjunction with an outer plastic retaining ring because stray current can no longer be harmlessly dissipated through the metal cannula directly to the surrounding peritrocar abdominal wall, and hence any juxtaposed visceral structure may be damaged in an area remote to the laparoscopist’s vision.**

Hand-Assist Approach. When the hand-assist device is in place, then secondary trocars can be placed with digital guidance. After inspection of the abdomen rules out any potentially interfering adhesions, the surgeon’s index finger is placed on the underside of the abdominal wall at the planned site of trocar placement. A skin incision is made over the surgeon’s index finger and the nonbladed trocar is passed with the other hand and guided by the surgeon’s finger into the abdominal cavity. This is a very rapid and safe way to place all of the secondary nonbladed trocars.

Trocar Configuration

A number of different trocar configurations exist depending on whether one is performing transperitoneal or retroperitoneal upper abdominal laparoscopy or robotics. Details and diagrams of these configurations can be found in Chapter 61. Similarly, a number of trocar configurations exist for transperitoneal and extraperitoneal laparoscopic and robotic pelvic procedures, which are detailed in Chapter 115. Most important, regardless of the configuration chosen, is to ensure meticulous placement of the ports to minimize instrument clashing both intracorporeally and extracorporeally.

Robotic Considerations

If a robotic procedure is planned, then the camera port is a 12-mm trocar site and the two (or three if the fourth arm is used) auxiliary ports are 8 mm. **All the ports need to be placed 8 to 10 cm apart to reduce the possibility of the robotic arms clashing with each other.** In addition, if the patient is in a flank position, then the lowest port placement should not be inferior to the umbilicus or else the arm may be blocked from a full range of motion by the

patient's upside leg. An assistant's port is placed on a line either caudal or inferior to the robotic arms; placement of the assistant's port between the arms of the robot makes it quite awkward for the assistant to work and limits the range of motion of the assistant's instrument owing to clashing with the arms of the robot. Of note, all 8-mm robotic ports need to be advanced to ensure that the thick black marking on the shaft of the trocar is below the abdominal wall.

Laparoscopic Instrumentation

Instruments for Visualization

To create a laparoscopic image, four components are required: the laparoscope, light source, camera, and monitor. To record the image, video recorders, digital video disc, and video printers are available.

Laparoscope and Camera

Standard Systems. The most commonly used laparoscopes have 0- or 30-degree lenses (range, 0 to 45 degrees) and are available in sizes from 2.7 to 10 mm. Typically, the 30-degree lens provides the surgeon with a more complete view of the surgical field than the 0-degree lens, allowing the surgeon to peer around vascular structures by rotating the lens. Recently, newer deflectable laparoscopes have been developed in which the tip of the endoscope can deflect in four directions up to 90 degrees (EndoEYE Deflectable-Tip Video Laparoscope [Olympus, Melville, NY]); which offers many potential angles from which to view a structure, but requires an adept assistant. Another novel endoscope design is the EndoCAMEleon (Karl Storz). This scope maintains the familiar feel of a standard rigid laparoscope but has a variable-view swing prism that enables the surgeon to change viewing angles from 0 to 30, 45, 90, or 120 degrees. An advantage of the EndoCAMEleon is that it has a standard eyepiece, allowing it to be used with most camera systems.

With standard laparoscopes, image transmission uses an objective lens, a rod-lens system with or without an eyepiece, and a fiberoptic cable. From the eyepiece, the optical image is magnified and transferred to the camera and onto the monitor. Light is transmitted from the light source through the fiberoptic cable onto the light post of the laparoscope (Fig. 10-19A on the Expert Consult website). Some newer laparoscopes have a mini charge-coupled device (CCD) camera mounted at the tip (EndoEYE [Olympus]), which improves image quality and avoids the need for an external light chord that can sometimes impede the movement of other instruments (Fig. 10-19B on the Expert Consult website).

The most vexing problem with any laparoscope is fogging of the lens. To prevent fogging of the laparoscope after insertion into the warm intraperitoneal cavity, it is advisable to initially warm the laparoscope in a container holding warm saline before it is passed into the abdomen. The most efficient way to warm the laparoscope is to use a dedicated solution warming basin that is long enough to accommodate the laparoscope; alternatively a warming thermos can be used (Applied Medical Resources). In addition, wiping the tip with a commercial defogging fluid or with povidone-iodine solution is also recommended. Should moisture buildup occur between the eyepiece and the camera, both components must be disconnected and carefully cleansed with a dry gauze pad; this is not a problem with the digital endoscopes because the only connection is from the endoscope directly into the display box.

A final important note is to ensure that the sterile scope is white balanced.

The camera system consists of a camera and a video monitor. All currently made cameras can be gas or liquid sterilized, thereby facilitating their use and limiting possible intraoperative contamination. For standard laparoscopes the camera is attached directly to the end of the laparoscope and transfers the view of the surgical field through a cable to the camera box unit. After reconstruction of the optical information the image is displayed on one or two video monitors.

Three-Dimensional Laparoscopic Systems. Three-dimensional laparoscopic systems offer the surgeon the distinct advantage of depth

perception. Optimal 3D laparoscopy is performed with a two-lens system that duplicates the two-eye perception of 3D. In this way binocular vision is maintained. The most commonly used 3D vision system currently in use is the InSite Vision System (Intuitive Surgical), which provides vision for the da Vinci Robotic System. The laparoscope and high-definition camera are heavy (5.5 pounds for the high-definition scope and camera head) but are controlled by a robotic arm that is under direct control of the surgeon from the ergonomic console. The surgeon maintains a steady, magnified 3D view of the surgical field. Zero- and 30-degree lenses are currently available.

Handheld 3D laparoscopic systems are also available, but currently require the surgeon to wear headgear with miniature video screens to display the 3D image (EndoSite 3Di Digital Vision System [Viking Systems, La Jolla, CA]) or specialized passive polarized glasses while viewing the image on a 3D monitor (Karl Storz) (Fig. 10-20 on the Expert Consult website). A few recent studies (Honeck et al, 2012; Tanagho et al, 2012; Lusch et al, 2014) have demonstrated superior depth perception, spatial location, and precision of surgical performance with 3D systems compared with two-dimensional (2D) systems while completing laparoscopic tasks in an ex vivo setting.

Instrumentation for Grasping and Blunt Dissection

Most graspers and dissectors are used in their 5-mm size, but are available in a range from 3 to 12 mm, in predominantly reusable forms. Grasping instruments have either single-action (only one jaw moves during opening) or double-action (both jaws move) tip design.

Wide variations exist with regard to configuration of tip, surface characteristics of jaws, handle design, and possible electrosurgical properties. Tip designs include blunt-coarse, pointed (dolphin), straight (duck bill), curved (Maryland), and angled. The surface of the jaws may be atraumatic or traumatic. Serrated or smooth surfaces allow gentle tissue manipulation in atraumatic graspers (e.g., bowel forceps with a 3-cm long grasping jaw). Traumatic graspers have toothed or clawed surfaces on their jaws to allow them to grasp and hold tissues firmly. In addition, each of these instruments may be equipped with tip-rotation and/or articulating features. Both reusable and disposable instruments are available.

Depending on the design of the handle, grasping instruments may be locking or nonlocking. Most nonlocking forceps have a scissor-type handle. Different designs allow for locking capabilities; in particular, bar-type and spring-loaded locking handles are convenient when prolonged grasping of tissue is required. Some newer dissectors in addition to grip and rotation actually offer additional degrees of freedom by means of an articulating joint activated through wrist movements of the surgeon (RealHand [Novare Surgical Systems, Cupertino, CA]; Autonomy Lapar-Angle [Cambridge Endoscopic Devices, Framingham, MA]). **These instruments are most helpful if one is to perform a LESS procedure because the angulation of the shaft then provides the triangulation necessary for approaching the surgical field.** In addition, the shafts of these instruments may be of variable length (i.e., 34, 45, or 75 cm), again allowing for less clashing of handles during a LESS procedure.

In addition to standard dissecting instruments, both the laparoscopic suction apparatus and the "heel" of the hook electrode can be used for effective and rapid blunt dissection. Along these same lines, the development of laparoscopic "peanuts" or Kittners (i.e., 5- and 10-mm gauze-tipped disposable dissectors) has been most helpful. These dissectors can be twirled or moved side to side or up and down in an area of adipose tissue to rapidly tease away the fat surrounding vital structures such as the renal hilum or the adrenal gland. In addition, the device can be used to raise an entire "line" of tissue (e.g., pararenal fat), allowing for its rapid and safe division because neither the shaft nor tip of the Kittner will conduct electrosurgical current.

Water jet dissectors, such as the Helix Hydro-Jet (ERBE Elektromedizin, Tübingen, Germany), use an extremely thin, high-pressure laminar liquid jet to develop a cleavage plane in tissues. Pressures

Figure 10-19. A, Standard rod and lens laparoscope and camera. B, Laparoscope with a mini-charge-coupled device camera mounted at the tip.

Figure 10-20. Handheld 3D laparoscopic systems. (Courtesy Karl Storz, Tuttlingen, Germany.)

of 250 to 350 psi are sufficient for dissecting soft tissue while leaving vascular structures and nerves intact (Shekarritz et al, 2004). The device is activated using a foot pedal and the water jet is administered from a 5-mm wand. This device may have particular application in parenchymal transection as in partial nephrectomy or in nerve-sparing procedures such as during retroperitoneal lymph node dissection (Basting et al, 2000; Shekarritz et al, 2004). However, owing to fluid accumulation in the abdomen, changes in tissue turgor and, in particular, splash back from the fluid stream that can foul the laparoscope lens, these devices have not come into widespread use.

Instrumentation for Incising and Hemostasis

Laparoscopic scissors, scalpels, electrocautery, ultrasonic devices, and lasers (CO₂, neodymium:yttrium-aluminum-garnet [Nd:YAG], or potassium titanyl phosphate [KTP]) are used to incise or cut tissue during laparoscopic surgery. Cutting of tissue with electrocautery and lasers is achieved when the cell temperature is elevated until the concomitant gas pressure causes the cells to explode. Conversely, with ultrasonic devices the cutting mechanism is a relatively sharp blade vibrating at 25 kHz to 55 kHz over a distance of up to 100 μ m.

Monopolar and bipolar electrocautery and other technologies exist for achieving hemostasis. The basic mechanism for coagulating bleeding vessels is similar among the various modalities, in that vessels are sealed and occluded with denatured protein; however, the manner in which protein is denatured is different for each modality. Electrosurgery and lasers denature protein by heating the tissues with electric current in the former and light in the latter, at a very high temperature. Conversely, ultrasonic devices denature protein by transferring mechanical energy to ultrasonic high-frequency vibration (25 kHz to 55 kHz).

Sharp Dissectors. Laparoscopic scissors are available in disposable and nondisposable forms. The blades of laparoscopic scissors are shorter than their open surgical counterparts. The configuration of the tip may be useful for selected situations: hooked tips for cutting sutures, microscissors for spatulating the ureter during a pyeloplasty, and curved tips for dissection. The scissors may come with either permanent blades or with replaceable tips; use of the latter ensures “sharp” scissors for each procedure. In addition, the shaft of the scissors may rotate and, in some disposable scissors, even articulate up to 90 degrees. A **laparoscopic scalpel** is also available.

Monopolar Electrosurgical Devices. For electrosurgical incision of tissue, a selection of different electrodes are available: needle electrodes (Corson type) produce fine cuts that are useful in making peritoneal incisions, spatula electrodes are used in blunt dissection and cutting, and hook electrodes (J and L configurations) are of particular value during dissection of vessels because tissue can be pulled away from delicate structures before the cutting current is activated. **The thinner the metal tip of the probe, the higher the density of the electrical current, and the greater the cutting power.**

As with all insulated instruments, certain precautions must be followed during monopolar electrosurgery to avoid local or distant transmitted thermal injury. Consequently, **the electrosurgical probe should not be activated unless the metal part is in complete view. The insulation of the electrosurgical instrument should be carefully checked for any damage. The probe should not be activated unless it is in direct contact with the tissue to be incised.**

To avoid the potential dangers of stray current from use of monopolar electrosurgical equipment, the surgeon can use monopolar current in conjunction with active electrode monitoring (Encision, Boulder, CO). This instrumentation is constructed such that there is ongoing feedback during activation of the electrosurgical current; therefore, any break in the insulation of the shaft results in immediate deactivation of the instrument.

For monopolar electrosurgical coagulation, the floating ball electrode (Salient Surgical Technologies, Dover, NH), which is a saline-cooled radiofrequency surface coagulator-sealer, also exists. Skimming the floating ball over a tissue surface in small circles seals

the tissue, stopping the flow of blood and other fluids by effectively shrinking the natural collagen in the tissue. The wet energy cools tissue and keeps temperatures below 100° C, preventing tissue charring and eschar formation. This device has been proven to be quite useful for coagulating the parenchymal bed after partial nephrectomy before application of a hemostatic agent and/or bolster (Stern et al, 2004; Urena et al, 2004).

Bipolar Electrosurgical Devices. The laparoscopic surgeon can also use bipolar electrosurgical devices that require less energy for performance than their monopolar counterparts. There is also a decreased likelihood of injury to surrounding tissue for a couple of important reasons. First, because the **electrical current is only passing from one jaw of the instrument to the other, it precludes the potential problem of capacitive coupling**, commonplace with monopolar electrosurgical current. Second, **with bipolar current, the extent of coagulative damage is less than with monopolar electrosurgery: 1 to 6 mm versus 5 to 7 mm with monopolar current** (Landman et al, 2003a).

One of the currently available bipolar electrosurgical devices is the LigaSure vessel-sealing system (Covidien) (Fig. 10-21 on the Expert Consult website). It consists of a 5- or 10-mm grasper-dissector connected to a bipolar radiofrequency generator. When the vascular structure is grasped by the instrument, the tissue is evaluated by a feedback-response system that subsequently delivers the optimal energy required to seal the vessel effectively. Because of the high-current and low-voltage output, the vascular structure enclosed by the jaws of the instrument degrades quickly and a protein-based seal is presumably created; this mechanism of electrical current delivery to the tissues results in less charring and less collateral thermal damage (1 to 3 mm) (Landman et al, 2003a). Indeed, use of this instrument during partial nephrectomy does not compromise the ability of the pathologist to read the surgical margin (Phillips et al, 2008). An audible signal alerts the surgeon that the sealing of the vessel is complete; the instrument has a trigger-activated blade that the surgeon can then use to cut the sealed tissue. Vessels up to and including 7 mm in diameter appear to be effectively occluded, to above normal physiologic pressures, with this device (Carbonell et al, 2003; Landman et al, 2003a). However, only one LigaSure application to the structure being sealed is recommended, because multiple applications may weaken the seal (Truong et al, 2008).

Another simultaneous vessel sealing and cutting device is the EnSeal PTC (Ethicon). This is a 5-mm instrument that can also act as a grasper-dissector. The electrode design uses a temperature-sensitive polymer that helps to limit current spread to surrounding tissues. The device has an I-beam-shaped blade that draws the jaws of the instrument together with increasing force as the blade is advanced through the tissue. Hence, the surgeon can control the rate of cutting by how quickly the instrument handle is squeezed. The device can be used to seal vessels up to 7 mm but is reported to require a longer vessel sealing time than the LigaSure V (Covidien) (Lamberton et al, 2008).

Laser Instrumentation. Lasers are most frequently used through the working channel of an operating laparoscope. The CO₂ laser provides excellent cutting and vaporization of surface lesions and requires a rigid hand piece and probe. In contrast, the 400- and 600- μ m KTP fibers are flexible and allow for noncontact cutting and fulguration. Nd:YAG laser fibers are also flexible and allow noncontact fulguration and contact cutting. Holmium laser fibers are also flexible and are used in a contact mode for cutting. Typically, lasers are not used in urologic laparoscopy, where they have largely been supplanted by electrosurgical instruments. Only in gynecology is the CO₂ laser used extensively, in general in the treatment of endometriosis.

Ultrasound Instrumentation. Ultrasonic technology (Harmonic scalpel, Ethicon; and Sonicbeat, Olympus, Center Valley, PA) is another option for cutting and hemostasis in endoscopic surgery. It provides an especially attractive alternative to monopolar electrosurgery when one is working around particularly delicate tissues or operating on patients with an implanted pacemaker or cardioverter defibrillator (Gossot et al, 1999; Strate et al, 1999). In ultrasonic

Figure 10-21. A, Example of a LigaSure vessel-sealing system. B, LigaSure tip. (A, Courtesy Covidien Ltd., Mansfield, MA. All rights reserved. Used with permission of Covidien.)

devices, electrical energy is transformed into mechanical energy by the use of a piezoelectric crystal system. Specifically, electrical energy is produced by a power-supply generator and transformed into mechanical vibration at the tip of the instrument through a piezoelectric crystal interface (Suzuki et al, 1995; Takeda et al, 1997; Gossot et al, 1999). Mechanical vibrations produced by this system in the tip of the instrument are capable of causing cavitation, coaptation and coagulation, and cutting in the targeted tissue (Strate et al, 1999). There are several important benefits to the ultrasonic system. These include the absent risk of local thermal damage and tissue charring because of a working temperature lower than 80° C. Subsequently, reduced tissue charring may result in a reduced rate of postoperative adhesions (Amaral and Chrotstek, 1997). A second benefit is that the depth of penetration is limited to the targeted tissue within a diameter of 1 mm, so there is minimal lateral thermal spread and potential for tissue damage (Landman et al, 2003a). Ultrasonic devices also minimize smoke for improved visibility in the surgical field. In addition, the ultrasonic systems eliminate other problems associated with monopolar electrosurgery, specifically, problems of remote site tissue damage caused by capacitive coupling, insulation defects in the instrumentation, and direct coupling. Lastly, as with bipolar energy, use of ultrasonic energy during partial nephrectomy does not compromise the ability of the pathologist to read the surgical margin (Phillips et al, 2008).

Potential disadvantages of ultrasonic technology include slower vessel sealing (Lamberton et al, 2008) and the fact that the metal portion of the shears becomes quite hot during activation (often over 200° C compared with the bipolar energy-based devices, which stay below 100° C) and must not come into direct contact with any bowel surrounding the area of dissection. In fact, the harmonic shears take roughly twice as long to cool to a “safe” temperature after firing (often up to 45 seconds) compared with the LigaSure device (Covidien) (Kim et al, 2008).

Combined Devices and Other Instrumentation. See the Expert Consult website for details.

Surgical Pharmaceuticals

Recently, a vast array of topical hemostatic agents and sealants that can be used for a variety of surgical tasks have entered the surgical realm and have become valuable additions to the surgeon’s tray. A comparison of popular hemostatic agents is presented in Table 10-1.

See the Expert Consult website for further details.

Instrumentation for Suturing and Tissue Anastomosis

Needle Drivers. Suturing and knot tying are among the most difficult tasks in laparoscopic surgery. A significant amount of practice

is needed to achieve a sufficient level of proficiency. **Laparoscopic needle holders** have one fixed jaw and one jaw that opens by squeezing the spring-loaded handle of the instrument. They all have a locking mechanism to secure the needle in their jaws; this is done with a ratchet, spring-loaded, or Castroviejo-type mechanism. Some needle holders also possess a feature that allows the jaws to rotate around the main axis relative to the handle. The handles may be straight or provide a pistol-type grip (Fig. 10-22 on the Expert Consult website). In addition to standard rigid needle drivers, some companies have recently developed articulating needle drivers that aid in obtaining more optimal suturing angles with the needle. The actuation of the articulation mechanism is controlled by the surgeon’s wrist motion (Laparo-Angle [Cambridge Endoscopic Devices]; RealHand [Novare Surgical Systems]).

Endo Stitch. The Endo Stitch (Covidien) device is an innovative, disposable, 10-mm instrument that facilitates laparoscopic suture placement and knot tying (Adams et al, 1995). With increased experience with standard laparoscopic needle holders and especially with the advent of robotic-assisted procedures, use of the Endo Stitch has become less common.

See the Expert Consult website for further details.

Lapra-Ty clips. Lapra-Ty clips (Ethicon) are a very useful adjunct to suturing and knot tying. The clip acts as a knot, thereby precluding time-consuming intracorporeal laparoscopic knot tying (Fig. 10-23). These 3.5-mm clips are made of absorbable polydioxanone and are designed to provide secure anchoring of sutures for up to 14 days in low-tension to mid-tension environments (Ames et al, 2005). According to the manufacturer, these suture anchors can be secured to the end of a single strand of polyglactin 910 (Vicryl) suture as fine as 4-0. Experimental models from two different laboratories have shown that these clips are least likely to fall off polyglactin 910 sutures from size 1-0 to 3-0 (Ames et al, 2005; Weld et al, 2008). In the laboratory environment Lapra-Ty clips have been shown to be slip resistant with 2-0 Monocryl and polydioxanone suture (PDS) as well. In multiple test trials for each suture type, a percentage of monofilament sutures size 3-0 and smaller as well as 4-0 suture of any type did have slippage of the clip. Hence, it seems logical to avoid Lapra-Ty use with 4-0 suture and to avoid excessive tension when using these clips with 3-0 monofilament suture. Lapra-Ty clips can be used to secure a single suture or a running suture and for anchoring bolsters during renorrhaphy for laparoscopic or robotic partial nephrectomy (Orvieto et al, 2004).

Instrumentation for Stapling and Clipping

Stapling Devices. Various stapling devices are available for tissue occlusion and division. The Endo GIA Universal 12-mm stapler and

TABLE 10-1 Some Commonly Used Topical Tissue Sealants and Hemostatic Agents

AGENT	MANUFACTURER (TIME TO SET UP)	ACTIVE INGREDIENTS	KEY USES AND PROPERTIES
Tisseel	Baxter, Glendale, CA (20 min)	Fibrinogen CaCl Aprotinin Thrombin	Topical hemostasis Tissue glue
Crosseal	Johnson & Johnson, New Brunswick, NJ (Immediate)	Fibrinogen CaCl Aprotinin Thrombin	Topical hemostasis Tissue glue
Floseal	Baxter (2 min)	Cross-linked gelatin granules Thrombin	Topical hemostasis
EndoAvitene	Davol, Cranston, RI (Immediate)	Avitene microfibrillar collagen powder	Topical hemostasis
BioGlue	CryoLife, Kennesaw, GA (Immediate)	Bovine serum albumin and glutaraldehyde	Tissue sealant
Coseal	Baxter (Immediate)	Two polyethylene glycol polymers	Tissue sealant

CaCl, calcium chloride.

A recently developed device called Thunderbeat (Olympus, Center Valley, PA) combines ultrasonic and advanced bipolar energies into a single multifunctional instrument allowing surgeons to seal and cut vessels up to and including 7 mm in size with minimal thermal spread. Initial porcine studies have shown the Thunderbeat to surpass the dissection speed of ultrasonic devices while having the sealing efficacy of bipolar devices ([Milsom et al, 2012](#); [Seehofer et al, 2012](#)).

The **argon beam coagulator** provides a noncontact form of electrocoagulation. Electrical current originating from a monopolar electrosurgical generator is conducted to the tissue through an ionized argon gas stream. The gas stream blows away blood from the tissue, resulting in better exposure of the bleeding site and

hence more effective delivery of the electrosurgical current. Argon is a colorless, odorless, inert gas that clears the body within one respiratory cycle ([Quinlan et al, 1992](#)). Holding the hand piece at an oblique 60-degree angle within 1 cm of the surface of the target tissue provides optimal coagulation effects. During argon beam coagulation, the sidearm on one of the laparoscopic ports must be opened to prevent buildup of excessive intra-abdominal pressures. Because argon beam coagulation has its major advantage when hemostasis must be achieved over a diffusely bleeding surface, its most practical indication in laparoscopic urologic surgery is during partial nephrectomy or for control of small liver or spleen lacerations.

Fibrin-Based Glue. Fibrin glue has been used to promote hemostasis in parenchymal beds, in particular after partial nephrectomy or to seal a liver laceration. The two components of the fibrin glue, fibrinogen and thrombin, are delivered through separate channels and then combine at the tip of the delivery system during application to the tissue. Fibrin glue provides topical hemostasis and has sealant and adhesive qualities once dry; it essentially hardens into a rubbery coagulum. Tisseel VH Fibrin Sealant (Baxter, Glendale, CA) has the maximum concentration of human fibrinogen available (75 to 115 mg/mL). It can be delivered by means of a laparoscopic applicator in liquid form or in an aerosolized form. One disadvantage of Tisseel is that it requires 15 minutes to prepare before the surgeon can apply it. If immediate application is required (e.g., because of bleeding), then fibrin glue is not a viable option unless it has been prepared in anticipation of possible hemorrhage. Once prepared, Tisseel VH is available for use for 4 hours.

Another fibrin-based sealant that can be delivered in a similar manner is Evicel (Johnson & Johnson, New Brunswick, NJ). This agent contains 40 to 60 mg/mL of human fibrinogen and is the only all-human, aprotinin-free fibrin sealant. Because it contains no bovine serum components (e.g., aprotinin) it can be used in individuals with allergies to bovine-derived products. Another advantage of this sealant is it comes frozen and thus requires no reconstitution. It can be thawed in the hand in 5 minutes and available in another minute. Once thawed, Evicel has a shelf life of 1 month under refrigeration (Tredree et al, 2006). This product can also be applied laparoscopically with an available applicator.

Although all types of fibrin glue use pooled human fibrinogen, the preparations are treated to inactivate viruses. As of 2006 there had been no reported cases of viral transmission to a recipient (Tredree et al, 2006).

Non-Fibrin-Based Surgical Hemostats. In contrast to the fibrin-based glues, other hemostatic agents such as thrombin-soaked oxidized cellulose particles (FloSeal [Baxter]; Surgiflo [Johnson & Johnson]) have no adhesive capability but are excellent hemostatic agents in the presence of active bleeding from parenchymal surfaces such as a partial nephrectomy bed, a liver or spleen laceration, or an oozing adrenal bed. These agents are composed of both human-derived thrombin and bovine- or porcine-derived gelatin matrix. The gelatin granules swell 10% to 20% to produce a tamponade effect, whereas the high concentration of thrombin promotes conversion of fibrinogen to fibrin, as well as activating platelets and several coagulation factors. This agent is also prepared by the scrub assistant; it takes 2 minutes to prepare and is usable for 2 hours. It is applied through a tube applicator with a syringe. It is most effective when pressure is applied after its delivery; this can be done either with an instrument (e.g., 10-mm gauze-tipped dissector) or with a bolster.

The Avitene Microfibrillar Collagen Hemostat (Davol, Cranston, RI) is an active collagen hemostat that accelerates clot formation by enhancing platelet aggregation and the release of fibrin. Similar to FloSeal, it has no tissue sealing capability, but is useful for counteracting parenchymal bleeding. EndoAvitene is available for use in endoscopic procedures. EndoAvitene comes prepared in a pre-loaded endoscopic delivery system, developed to easily pass through standard trocars and cannulae. It is available in both 5- and 10-mm diameters.

Chemical-Based Sealants. BioGlue (CryoLife, Kennesaw, GA) is a two-component adhesive composed of purified bovine serum albumin (BSA) and glutaraldehyde. The solutions are mixed during application from a controlled delivery system. The glutaraldehyde then cross-links the BSA molecules to one another and then to the tissue protein at the site of use. Once applied, the agent polymerizes within 20 to 30 seconds and reaches its full bonding strength within 3 minutes. The delivery system comes ready for immediate use. BioGlue is a sealant and must be applied to a dry field and allowed to dry. Thus it cannot be used to counteract active bleeding but can be used to seal a raw, nonbleeding surface.

Coseal (Baxter) and AdvaSeal-S (Genzyme, Cambridge, MA) are completely synthetic products composed of two distinct polyethylene glycol polymers that chemically bond together to form a hydrogel that seals tissue surfaces, suture lines, and synthetic grafts. It does not require thawing, heating, or light activation and hence can be ready in 1 minute. It must be applied to a dry (nonbloody) surface because it does not interact with the clotting cascade and hence is not useful in the setting of active hemorrhage.

Now that the benefits of such substances have come into the spotlight in surgery, it is important for the surgeon to be familiar with the properties of these various agents and thereby able to choose one that is most appropriate for the job at hand.

Figure 10-22. Different handle designs for commonly used laparoscopic needle drivers. A, Straight handle reusable (top) and disposable (bottom). B, Pistol-type grip.

The suture is secured to the center of a straight needle with two pointed ends, thereby allowing tissue penetration in either direction. The needle is shuttled back and forth between the jaws of the instrument after each passage through the tissue, applying a long-known principle used in sewing machines. In this way, passing the needle through the tissue and regrasping the needle after it has traversed the tissue become simple tasks because they are done by a one-handed squeeze of the handle and a flip of the needle-securing lever, respectively. Use of this sewing apparatus has had a major impact on decreasing operative times, especially in laparoscopic pyeloplasty ([Chen et al, 1998](#)).

linear cutting device (Covidien) requires a 12-mm port and delivers two triple-staggered rows of staples and simultaneously cuts between the rows (Fig. 10-24). The Universal stapler can be loaded with a variety of 30-, 45-, or 60-mm loads and fired any number of times. Similarly, the ETS-Flex 45 stapler (Ethicon) also requires a 12-mm port and delivers two triple rows of staples while cutting between

rows 3 and 4. This stapler has a maximum fire limit of eight staple loads. Articulating and roticulating staplers are available from both companies, which enable the surgeon to properly align the instrument with the tissue to be occluded and divided. Each staple load cartridge is color coded depending on the size of the staples: 2.0-mm staples (gray) or 2.5-mm staples (white) are preferred for vascular (renal vein or renal artery) stapling, whereas 3.8-mm (blue) and 4.8-mm (green) staples are used in thicker tissues (ureter, bowel, bladder). In addition, for laparoscopic live donor nephrectomy, a single Endo-TA (linear noncutting) stapler can be used to secure the patient's side of the renal vein, thereby providing a longer donor renal vein, because there is no need to trim staples from the vessels before anastomosis in the recipient (Meng et al, 2003). Linear noncutting staplers deliver either three or four staple rows, 30 or 60 mm long. These staplers can also be used to close an enterotomy after a side-to-side bowel anastomosis. When laparoscopic staplers are used, special attention must be paid to the markers on the cartridge to ensure that all the targeted tissue is properly situated proximal to the markers before the cartridge is fired. The stapler should not be fired across any previously placed clips because this is thought to possibly cause stapler malfunction. Indeed, in a 9-year review of stapler use (1992 to 2001), Brown and Woo (2004) noted U.S. Food and Drug Administration–recorded reports of 112 mortalities and 2180 injuries attributed to use of the stapler; overall, malfunctions were reported 22,804 times.

Clipping Devices. Disposable and nondisposable clip applicators are available from different manufacturers and require 5-, 10-, or 12-mm laparoscopic ports. In general, they contain occlusive clips ranging in size from 6 to 11 mm. Disposable clip applicators possess a rotating shaft and multifire, self-reloading features, whereas nondisposable instruments have to be reloaded for each clip to be deployed at the site of surgery (Fig. 10-25).

Electrocoagulation must be avoided in the vicinity of clips placed for occlusion of vessels to prevent conductive tissue necrosis and subsequent clip dislocation. To ensure reliable function, the closed ends of the occlusive clips must be seen extending slightly beyond the targeted vessel and should be placed perpendicular to the longitudinal axis of the vessel.

In addition to titanium clips, polymer clips that completely encircle and lock down around a vessel are available (Weck Hem-o-lok polymer ligation clip system [Teleflex, Research Triangle Park, NC]) (see Fig. 10-25). They are available in four sizes (M, ML, L, and XL). Up to 10 mm of tissue can be ligated through a 5-mm trocar, and up to 16 mm of tissue can be ligated through a 10-mm trocar. Of note, because of results from a survey put forth by the American Society of Transplant Surgeons, in which use of these clips was associated with hemorrhage from the renal artery stump, the company producing the clips put forth a statement contraindicating their use for securing the renal artery during laparoscopic live donor nephrectomies (Friedman et al, 2006). Subsequently, a multi-institutional study of 1695 patients from nine different institutions undergoing laparoscopic donor nephrectomy with ligation of the renal artery with Hem-o-lok clips concluded that the clips were safe to use because in this review there were no adverse bleeding events (Ponsky et al, 2008a). The authors did acknowledge, however, that proper technique of application must be strictly adhered to, including application of at least two clips on the stump of the artery, and that a 2-mm cuff of artery should be left distal to the clips (Box 10-2). Removal of a Hem-o-lok clip is possible using the specified removal instrument, should a structure be clipped in error.

Instrumentation for Specimen Entrapment

Various organ entrapment and retrieval systems are available. Depending on the size of the tissue and on whether in situ morcellation or intact organ retrieval is planned, the laparoscopic surgeon is able to choose among different-sized sacks, materials, and designs. Studies have been conducted to test organ retrieval bags for permeability to tumor cells and bacteria before and after

Figure 10-25. A, Weck Hem-o-lok clip and tip of laparoscopic applicator (top) (Teleflex, Research Triangle Park, NC) and metal clip and tip of laparoscopic applicator (bottom). B, Metal clip (top) and Weck Hem-o-lok clip (bottom) affixed to a suture.

BOX 10-2 Basic Principles of Hem-o-lok Clip Placement

- Complete circumferential dissection of the vessel
- Visualization of the curved tip of the clip around and beyond the vessel, often with curved end of the clip placed between artery and vein
- Confirmation of the tactile snap when the clip engages
- No cross-clipping
- Not squeezing clip handles too hard (compared with the application of metal clips)
- Careful removal of the applicator after application given; the tips are sharp and can cause a laceration of nearby vessels (e.g., renal vein)
- During transaction of vessels only a partial division is performed initially to confirm hemostasis before complete transaction
- Minimum of two clips placed on the patient side of the renal hilar vessel

From Ponsky L, Cherullo E, Moynadeh A, et al. The Hem-o-lok clip is safe for laparoscopic nephrectomy: a multi-institutional review. *Urology* 2008;71:593–6.

morcellation, as well as for stability during morcellation and resistance to tearing forces (Urban et al, 1993; Rassweiler et al, 1998b). The originally designed (1990) LapSac (Cook Urological, Spencer, IN), which is made of nylon with a polyurethane inner coating and a polypropylene drawstring, is the least susceptible entrapment sack to tearing (Eichel et al, 2004) or leakage of cells. Up to a 2-kg specimen can be secured within the LapSac; however, deployment of the LapSac and subsequent organ entrapment remain challenging endeavors.

Other entrapment sacks offer marked advantages when the only goal is organ entrapment and intact removal, rather than morcellation. These sacks have spring wires that, when activated by the surgeon, deploy the bag after its introduction into the abdomen; this facilitates tissue entrapment because the broad wire supports stabilize the opened sack, thereby allowing the surgeon to literally scoop the specimen into the sack (Fig. 10-26). The entrapped specimen can easily be withdrawn through a hand-assist site or by enlarging a laparoscopic port site, usually to 5 to 7 cm for most specimens.

Figure 10-26. Organ retrieval bag.

Instrumentation for Morcellation

Various techniques of tissue morcellation have been used in laparoscopic surgery. The simplest method for fragmentation of tissue within the entrapment sack is use of the index finger, ring forceps, or Kelly clamp. Recently, however, it has been shown that ring forceps are the preferred instrument for manual morcellation because they are less likely to puncture the entrapment sack (Eichel et al, 2004).

See the Expert Consult website for further details.

Instrumentation for Retraction

Many varieties of retractors with different features are available.

See the Expert Consult website for details.

Robotic Instrumentation

For the da Vinci Robotic System (Intuitive Surgical), a wide variety of articulating instruments are available. The proprietary EndoWrist technology offers articulation at the tip of the instruments with 7 degrees of freedom and 90 degrees of articulation, mimicking the wrist movements of the surgeon at the robotic console (Fig. 10-27). A full line of 8-mm EndoWrist instruments are available, but it should be noted that all robotic instruments for the da Vinci Surgical System (except the laparoscopes) have a 10-case limit before they must be replaced. The number of “lives” left on each instrument should be recorded with each case.

If morcellation is performed intracorporeally, the entrapment sack should be a LapSac; however, a variation reported by [Landman and colleagues \(2003b\)](#) for morcellation uses one of the plastic entrapment sacks. In this method, the morcellation is performed above the abdominal wall, by extending the extraction site incision to 3 cm in length. All tissue is fragmented and removed under direct vision above the abdominal surface; at no time is the morcellating instrument out of the direct vision of the surgeon. With this approach, specimens could be morcellated rapidly, with the entire entrapment and morcellation process taking only 13 minutes for clinical specimens as large as 700 g; also fragment size increased from 1.5 to 4.5 g, which might afford better tissue assessment with regard to capsular, vascular, or renal sinus fat invasion ([Landman et al, 2003b](#)).

For morcellation of a renal malignancy, the neck of the sack is triply draped to preclude any contamination: a towel drape, Ioban (3M), and nephrostomy drape can be used. At the end of the morcellation procedure, the surgeon and assistants regown and glove.

The use of an entrapment sac is important, because wound seeding with tumor has been reported with intact specimen extraction without entrapment ([Iwamura et al, 2004](#)). In contrast, there has been only one noted wound seeding with morcellation in a LapSac ([Fentie et al, 2000](#)), and a multi-institutional study comprising 2064 radical nephrectomies, among which 826 were removed by entrapment and morcellation, showed no instance of a wound seeding with tumor ([Micali et al, 2004](#)).

The simplest retractor is a metal bar with an atraumatic tip or a curved saddle shape; the latter is helpful for retracting a vessel during lymph node dissection. Similarly, the disposable laparoscopic “peanut,” in either its 5- or 10-mm rendition, is very helpful because it can both dissect and atraumatically retract tissue.

However, the most useful retractors are the expanding types: fan retractors with three or four atraumatic finger-like extensions, fan retractors with V-hinge joints, balloon retractors, and kite-style instruments (e.g., Padron Endoscopic Exposing Retractor [PEER] retractors) (Jarit, Hawthorne, NY) (Brooks, 1993). The 5-mm kite style retractor provides a 2- × 3-cm retracting area, whereas the 10-mm version provides a 4- × 3-cm retracting area. This type of retractor is very helpful for firm retraction, such as on the kidney to put the renal hilum on stretch.

Another type of retractor is malleable and thus can be shaped to the needs of the surgeon. The Diamond-Flex angled 80-mm triangular retractor (Snowden-Pencer Instrumentation, Carefusion, Waukegan, IL) can be adapted to many different angles, curves, and shapes, and the surgeon can lock in its particular configuration. This feature is of particular value when retraction of a delicate organ such as the liver is required. This instrument forms a broad retracting surface 8 cm in length.

Retraction of tubelike structures (e.g., vessels, ureter) can also be achieved by placing a suture, a vessel loop, or an umbilical tape

around the tissue and applying traction either with a grasper inside the abdomen or by pulling the ends of the retraction loop out of the abdomen through a small stab incision using a Carter-Thomason device (Carter, 1994) or by encircling the structure with a suture affixed to a Keith needle, which can be passed across the abdominal wall, around the structure to be retracted, and then back out the abdominal wall (see later discussion of exiting the abdomen). The retraction loop can then be secured under slight tension on the surface of the abdomen with a small hemostat. Care should be taken during the use of this technique because excessive tension may injure the structure being retracted.

Mechanical Assistants. External mechanical devices such as the EndoHolder (Codman, Raynham, MA) or the Laparostat (Civco, Kalona, IA) can be used to keep grasping forceps or locking retractors in position, thereby taking the place of a tableside assistant. This device is usually mounted on the side of the table opposite the surgeon. The malleable free arm is then affixed to the shaft of a grasping forceps or laparoscopic retractor. When the surgeon has used the retractor for its given purpose, the malleable arm of the external mechanical device is locked in place, thereby providing reliable, continued traction.

Instrumentation for Incising and Hemostasis

A variety of EndoWrist scissors and scalpels exist for incising tissue and include the round tip, curved and Potts scissors, and the Snap-fit scalpel instrument. EndoWrist monopolar and bipolar electrocautery instruments are available for incision, dissection, and hemostasis during procedures. Monopolar instruments include the Hot Shears curved scissors and cautery hook and spatula. Bipolar instruments include the Maryland, PK dissecting (Intuitive Surgical), fenestrated, micro, PreCise and curved bipolar forceps. An ultrasonic device (Harmonic ACE curved shears [Ethicon]) is also available for dissection and hemostasis.

Instrumentation for Grasping and Blunt Dissection

A large array of EndoWrist graspers exist that cover the range of blunt to toothed and fine to gross, for use in varying situations. The most commonly used grasper in urologic procedures is the Pro-Grasp blunt forceps.

A safety feature on all robotic grasping devices is a small Allen bolt that can manually open the jaws of the instrument in the case of a robotic arm malfunction or loss of power in which the grasper is locked onto tissue or a needle at the time of failure. Of note, robot failure is quite rare. In the series from the University of Chicago, a robot failure was recorded in less than 1% of cases, and half of these problems (e.g., failure to power up, optical malfunction) were discovered before the patient entered the operating room. In addition, in the few instances in which there was a system malfunction (e.g., loss of 3D vision, robotic arm failure) during the case (0.4%), the procedure could still be completed without converting to an open procedure (Zorn et al, 2007).

Instrumentation for Suturing and Tissue Anastomosis

Four different EndoWrist needle drivers are available for suturing. There are two sizes of needle drivers available in both the standard

and SutureCut design. The SutureCut design allows the surgeon to be able to cut the suture material using the crotch of the instrument.

Other Available 8-mm and 5-mm Instruments

A number of other robotic instruments are also available. Endo-Wrist clip appliers exist for both small titanium clips and medium-large and large Weck Hem-o-lok polymer clips (Teleflex). In addition, an articulating suction device and irrigator, a probe stabilizer, and specialty retractors exist.

A 5-mm line of instruments is also available that is slightly more limited, but still offers a relatively complete line of instruments. It should be noted, however, that the 5-mm robotic laparoscope offers a 2D not 3D image.

Exiting the Abdomen

Port Removal and Fascial Closure

Port removal and fascial closure are key elements of the procedure that, if not performed in a step-by-step, organized fashion, can result in major, possibly fatal, complications. Herniation, possible bowel incarceration, and postoperative hemorrhage are the results of a poorly performed or haphazard, overly rapid exiting of the abdomen.

Before port removal is initiated, the operative site and the intra-abdominal entry sites of each cannula must be carefully inspected with the intra-abdominal pressure lowered to 5 mm Hg. After achievement of perfect hemostasis, removal of all laparoscopic ports must be undertaken strictly under laparoscopic visual control, to avoid any possible acute herniation of intra-abdominal contents into the previous port sites.

Presently, with the shift away from bladed to nonbladed trocars, the need for fascial closure for even 12-mm ports has come into question. Most will recommend that on removal of any of the blunt-tipped ports, the fascia does not need to be sutured, except for ports larger than 10 mm placed in the midline. However, a report has shown that 12-mm ports, regardless of site (i.e., midline vs. transmuscular), do not require fascial closure, provided that postoperative palpation of the entry site reveals a small defect (Siqueira et al, 2004). In the literature, the switch from bladed to blunt trocars has resulted in a marked decrease in abdominal wall bleeding (from 0.83% to only 0.16%) and in port site hernia formation (1.83% to 0.19%) (Hashizume and Sugimachi, 1997; Thomas et al, 2003).

In the rare case in which bladed trocars are used, the fascia at all 10- to 12-mm port sites should be closed. After inspection at 5 mm Hg, the first 10- or 12-mm port is removed and the fascia at the entry site is secured with 0-0 Vicryl either by direct placement of a fascial suture or use of a suture-passing device (see later). Five-millimeter ports are not closed in the adult, but are closed in the pediatric patient with a single absorbable suture. Ideally, each fascial suture will be placed under direct endoscopic vision prior to definitive port removal. In this manner, each port is visually assessed for any bleeding at 5 mm Hg, thereby precluding the possibility of removing a port and missing an injured vessel. After removal of all ports, the CO₂ is allowed to pass out passively through the 5-mm port sites.

With regard to the hand-assist device, it should be removed before removal of the other port sites. The hand-assist device wound

A detailed description of access devices for LESS such as the TriPort and Uni-X has previously been presented in this chapter. By definition, in LESS, all of the instrumentation for the case including a camera and lens for visualization and the working instruments to perform the procedure must be placed through a single incision. This creates ergonomic challenges with regard to instrument collisions inside and outside the abdominal cavity. Furthermore, the typical trocar arrangement for laparoscopy, which affords one the ability to “triangulate,” is largely lost with LESS. Much of the emphasis on instrumentation for LESS therefore centers on minimizing instrument collisions outside the abdominal cavity and re-creating the “triangulation” necessary to approach the surgical site safely (Fig. 10-28).

With regard to endoscope choice, one issue encountered is that the light cord often attaches to the telescope at a 90-degree angle and can thus hinder the movement of the lens or other instruments. To avoid this problem one can use an endoscope that has the light cord attached end-on from the back directly into the endoscope (Karl Storz) or a one-piece endoscope that already has an end-on integrated light cord (EndoEYE, Olympus, Orangeburg, NY). Alternatively, an extra-long laparoscopic lens can be used to keep the light cord away from the shorter standard working laparoscopic instruments. Similarly, use of laparoscopic instruments of different lengths can help keep the handles from clashing with one another.

With regard to overcoming the parallel nature of the instrument paths and reestablishing a triangular arrangement of instrumentation, several technologic advances have been developed so far with endoscopes and instruments. In terms of endoscopes, a laparoscope with a deflecting tip (EndoEYE Flex [Olympus]) or adjustable angle tip (EndoCAMEleon [Karl Storz]) should be used because these telescope designs offer the greatest adjustability for optimal viewing. At the very least an angled lens (30- or 45-degree fixed angle) should be used. In terms of instruments, the use of articulating or curved instrumentation is essential to avoid instrument collision outside the abdomen and to achieve proper triangulation for tissue retraction, exposure, and dissection. Disposable articulating instruments are available from RealHand (Novare Surgical Systems) and Autonomy Laparo-Angle (Cambridge Endoscopic Devices). Curved reusable laparoscopic instruments are also available (Karl Storz-Endoskope; Sklar Instruments, West Chester, PA) and provide a nondisposable alternative to the articulating instruments, which are one-time-use items. Both single-curved and

Figure 10-28. Deflecting laparoscopic instrumentation can be used to maintain triangulation during laparoendoscopic single-site surgery. (Reprinted with permission, Cleveland Clinic Center for Medical Art & Photography ©1998-2011. All rights reserved.)

double-curved reusable instruments exist. In addition, the recent development of the SPIDER surgical system (TransEnterix, Morrisville, NC) provides a flexible laparoscopic platform for single-site surgery with restoration of triangulation. Disposable flexible, articulating instruments specifically designed for the SPIDER surgical system allow for transmission of force and torque via a flexible, catheter-based instrument with true left and right instrumentation and elimination of crossed arm movements.

Finally, the use of the robot for LESS procedures has been demonstrated. A recent systematic review revealed that a cumulative number of roughly 150 robotic urologic cases have been reported in the literature including pyeloplasties, partial nephrectomies, living donor, simple and radical nephrectomies, adrenalectomies, and radical prostatectomies (Autorino et al, 2013). The ability of the robotic arms to articulate is a major plus, and one can envision that LESS will follow the path of standard laparoscopy into the robotic age.

The concept of natural orifice transluminal endoscopic surgery (NOTES) is not truly new; indeed, the first NOTES procedure would have been Philipp Bozzini's cystoscopy in 1804. What is new is the use of flexible endoscopic technology to perform procedures heretofore unthinkable with a transgastric (e.g., appendectomy in 2004 by Rao and Reddy) or transvaginal approach (e.g., appendectomy in 2004 and cholecystectomy in 2007 independently by Bressler and then Marescaux). Over time these increasingly complex endoscopes have developed from purely diagnostic instruments for visualization of intraluminal surfaces to highly functional endoscopes capable of carrying therapeutic tools that can be used to treat visualized problems. Recently, further advances in this type of technology have led to the development of endoscopes specifically for transluminal surgery. The potential advantages of transluminal endoscopic surgery are better cosmesis, less pain, elimination of the risk for wound infection and hernias, and a reduction in adhesions (Swanstrom et al, 2008a, 2008b).

There are several prototype endoscopes currently under evaluation for NOTES. In general, these endoscopes offer larger working channels than standard endoscopes and allow larger instrumentation. Some endoscopes such as the Transport (USGI Medical, San Juan Capistrano, CA) are designed with a guidable locking overtube through which other instruments can be placed; within the 20-mm overtube there are four ports (7 mm, 6 mm, 4 mm, and 4 mm) to accommodate the endoscope and up to three additional instruments. One of the working channels houses a standard 6-mm endoscope for vision, and the other working channels are for instrumentation. Some endoscopes offer triangulating instrumentation. Major hurdles still exist in terms of developing better and more effective instrumentation and especially devices for suturing and enterotomy closure. The Transport, for instance, can be used to perform enterotomy closure using special suture anchors (g-Cath [USGI Medical]).

is then closed as one would close a typical abdominal wound. After closure, the pneumoperitoneum is reestablished and the other port sites are closed as previously described. Proceeding in this fashion precludes the chance of injuring the bowel or omentum beneath the hand-port site and ensures an airtight closure.

Instrumentation for Port Site Closure

Several possibilities for fascial closure of port sites exist. The **simplest method** is retracting the skin with retractors, grasping the fascia, and suturing it with absorbable 0-0 suture. However, in patients with a BMI above 30, securely accessing the fascia is very difficult to accomplish.

Fortunately, several devices for complete en bloc closure of fascia, muscle, and peritoneum under direct vision have been developed (Carter 1994; Monk et al, 1994; Garzotto et al, 1995; Elashry et al, 1996). These work well in patients of all sizes.

The **Carter-Thomason needle-point suture passer** (CooperSurgical, Pleasanton, CA) consists of a 5-, 10-, or 12-mm cone that has two integrated, hollow, angled, cylindric passages located 180 degrees opposite each other (Fig. 10-29). With the sharp needle-point, single-action grasper, the 0-0 Vicryl suture is inserted through one of the cylinders in the metal or plastic cone, thereby traversing muscle, fascia, and peritoneal layers in an ever-widening angle. The end of the suture is grasped with a 5-mm grasper through one of the other ports. The needle-point grasper is reintroduced through the other cylinder of the cone, and the intraperitoneal end of the suture is grasped by the needle-point grasper and pulled out of the abdomen. The cone is slid off both ends of the suture. Subsequently, closure of the fascia, muscle layer, and peritoneum is accomplished by tying the suture. **The Carter-Thomason needle-point device is not only helpful for wound closure, but also can be used as a fifth port during nephrectomy to help hold the sack open or to encircle the ureter with a vessel loop through a small stab incision.**

The **disposable Endo Close suture carrier** (Covidien) is a device with a spring-loaded suture carrier at its tip. Loaded with a suture, the device traverses fascia, muscle, and peritoneum alongside the port. After reinsertion on the opposite side of port entry, it is reloaded with the suture, aided by a 5-mm grasper, and is pulled out again so that the suture can then be tied.

A far simpler, less expensive, homemade solution is available to all surgeons for closing ports in a large patient. This **angiocatheter technique** applies the previously described principles. A 14-gauge, sheathed needle is passed alongside the port through the abdominal layers. After removal of the needle, a 0-0 Vicryl suture is inserted through the angiocatheter sheath until it is deep inside the peritoneal cavity. After the sheath is removed, the same maneuver is repeated on the opposite side, but this time a 30-inch 0-0 Prolene suture folded in half is passed into the peritoneal cavity through the sheath to act as a retrieving loop. A 5-mm grasper passed through another port is then passed through the loop of 0-0 Prolene suture and used to grasp the end of the 0-0 Vicryl suture. The 0-0

Vicryl suture is pulled through the Prolene loop and released. By pulling the Prolene loop upward through the angiocatheter sheath, the entrapped 0-0 Vicryl suture is then retrieved from the abdomen. After the angiocatheter sheath is removed, the two ends of the suture can be tied.

Closure of the Skin

The skin of all 10-mm port sites is closed with subcuticular 4-0 absorbable suture. Adhesive strips are applied to all port sites to close (for incisions <10 mm) or to further approximate (for incisions ≥10 mm) the skin. As an alternative, the skin can be closed using octylcyanoacrylate glue. This has been found to speed closure time and provide an equivalent cosmetic result compared with suturing (Sebesta and Bishoff, 2004).

KEY POINTS: PERFORMING THE PROCEDURE

- A checklist ensuring that all essential equipment is present and operational should be completed just before initiating the pneumoperitoneum. Additional items to check when using the da Vinci Robotic System include ensuring that all plugs for the console, vision cart, and patient-side cart are plugged into different circuits and that all cables connecting these carts are connected properly.
- After placement of the Veress needle, insufflation should never be initiated unless all of the signs for proper peritoneal entry (negative aspiration, easy irrigation of saline, negative aspiration of saline, positive drop test result, and normal advancement test) have been confirmed.
- The open technique is recommended specifically when extensive adhesions are anticipated.
- Noncutting dilating trocars have superseded bladed trocars because they are safer. These trocars enter the abdomen by spreading the abdominal wall musculature, rather than cutting it, and therefore there is less chance of injuring an abdominal wall vessel and the resulting entry site is less prone to subsequent herniation.

PHYSIOLOGIC CONSIDERATIONS IN THE ADULT

The rapidly expanding number of newly developed laparoscopic and robotic procedures in operative urology has resulted in an increasing need for urologists to familiarize themselves with both the physiology and the potential complications related to the pneumoperitoneum and patient positioning.

Choice of Insufflant

Carbon Dioxide

CO₂ is the most commonly used insufflant for laparoscopic surgery and is favored by most laparoscopists thanks to its properties (colorless, noncombustible, very soluble in blood, and inexpensive). Prolonged postoperative distention of the abdomen does not occur because CO₂ is quickly absorbed (Wolf and Stoller, 1994). It is highly soluble in water and easily diffuses in body tissues. It readily moves out of the peritoneal cavity, as a result of a high diffusion gradient caused by the difference in concentration of CO₂ between the intraperitoneal space and the surrounding components (e.g., blood). However, the characteristic of rapid absorption, which lessens the chance of a CO₂ gas embolus, may also lead to potential problems (e.g., hypercapnia, hypercarbia, associated cardiac arrhythmias). In particular, patients with COPD may not be able to compensate for the absorbed CO₂ by increased ventilation; this may result in dangerously elevated levels of CO₂ in these patients, thereby necessitating the direct testing of arterial blood gases during laparoscopy in the pulmonary compromised

Figure 10-29. Carter-Thomason device. Cone and needle-point single-action grasper in open position.

patient. Carbon dioxide also stimulates the sympathetic nervous system, which results in an increase in heart rate, cardiac contractility, and vascular resistance. Lastly, CO₂ is also stored in various body compartments (e.g., viscera, bones, muscles). After prolonged laparoscopic procedures it may take hours before the patient has eliminated the extra CO₂ that has accumulated in these storage areas; again, this is more often the case and a problem in patients with pulmonary compromise (Lewis et al, 1972; Puri and Singh, 1992; Tolksdorf et al, 1992; Wolf and Stoller, 1994). Therefore, as previously noted, all patients, and in particular those with pulmonary disease, must be closely monitored after a lengthy laparoscopic procedure for possible signs or symptoms of hypercarbia; indeed, their greatest chance of compromise as a result of hypercarbia may occur after extubation in the postanesthesia recovery room.

Alternative Gases

Nitrous oxide is less irritating to the peritoneum and causes fewer acid-base changes and cardiovascular adverse effects (e.g., arrhythmias) than CO₂ (Scott and Julian, 1972; El-Minawi et al, 1981; Minoli et al, 1982; Sharp et al, 1982). However, some studies have shown that nitrous oxide insufflation reduces cardiac output and increases mean arterial pressure, heart rate, and central venous pressure (Marshall et al, 1972; Shulman and Aronson, 1984). Because nitrous oxide supports combustion, it can be used only during laparoscopic procedures that do not involve the use of electro-surgical instruments.

Helium is an inert and noncombustible insufflant. Initial studies performed in various animal models showed favorable effects on arterial partial pressure of CO₂ and pH with **no evidence of hypercarbia** (Fitzgerald et al, 1992; Leighton et al, 1993; Rademaker et al, 1995). These results were corroborated by clinical studies (Bongard et al, 1991; Fitzgerald et al, 1992; Leighton et al, 1993; Neuberger et al, 1994; Rademaker et al, 1995; Jacobi et al, 1997). Therefore, helium is particularly useful for the patient with pulmonary disease in whom hypercarbia would be poorly tolerated. In a relatively recent study from Johns Hopkins University, 10 patients at high risk for hypercarbia underwent laparoscopic renal surgery with helium insufflation. These patients were successfully managed, with only one patient developing an end-tidal CO₂ over 45 mm Hg (Makarov et al, 2007). Likewise, if hypercarbia develops during a laparoscopic procedure with CO₂, rather than aborting the procedure or converting to an open approach the surgeon can change the insufflant to helium and usually salvage the case (Brackman et al, 2003). There is also evidence that the use of helium may cause a decrease in tumor cell growth and inflammatory reactions within the peritoneal cavity (Jacobi et al, 1997, 1999; Dahn et al, 2005). Helium insufflation can be used for laparoscopic procedures (e.g., cholecystectomy, appendectomy, hernia repair) performed with local and regional anesthesia in high-risk patients, not only because of its favorable metabolic features, but also because of its lack of peritoneal irritation and its association with decreased postoperative pain (Crabtree and Fishman, 1999). However, laparoscopists have to bear in mind that helium may be associated with a higher risk of gas embolism because of its **lower blood solubility**. When helium is going to be used, it is advised to initially obtain the pneumoperitoneum with CO₂ and then change to helium, thereby lowering the chances of a helium gas embolus. Also, helium is significantly more expensive than CO₂. Lastly, with use of helium a separate “yoke” (i.e., line from the gas tank to the insufflator) is needed; accordingly, one needs to make sure that a “helium yoke” is available in the operating room or make arrangements to have one provided when performing laparoscopy on patients with severe pulmonary compromise. In practice, the use of helium may be quite difficult; however, argon may also be used in circumstances when hypercarbia occurs. Indeed, the gas from the argon beam coagulator can be used to maintain the pneumoperitoneum. However, with argon being an inert gas, like helium, the same precautions apply (Badger et al, 2008).

Other insufflants (e.g., room air, oxygen) have been used to establish a pneumoperitoneum in the past. However, possible

serious side effects (e.g., air embolus, intra-abdominal explosion, combustion with oxygen and room air) have terminated their clinical use. Other options for insufflants include some of the other noble gases (e.g., xenon, argon, and krypton), which are inert and nonflammable; however, their widespread clinical use has not been adopted because of their high cost and poor solubility in blood.

Choice of Pneumoperitoneum Pressure

Overall, the most commonly selected pressure for performing laparoscopy is 15 mm Hg; however, recent studies support a pressure of 12 mm Hg as more optimal, because this results in no perturbations in cardiac parameters (i.e., no change in stroke volume) versus a pressure of 15 mm Hg (Mertens zur Borg et al, 2004). Working at lower pneumoperitoneum pressures has also been found to reduce postoperative pain (Sarli et al, 2000). Using an even lower working pressure of 10 mm Hg has been shown to result in a marked reduction in oliguria (McDougall et al, 1994), but this is likely at the expense of smaller working space. Conversely, a pressure of 20 mm Hg has been noted to produce a 22% increase in insufflant filling volume and possibly less venous bleeding during the procedure (Adams et al, 1999). However, the absolute benefit of increased insufflant filling is debatable; McDougall and colleagues (1994) noted that, despite the increased volume, there was only a very small increase in abdominal girth at higher pressures.

Various cardiovascular, renal, and respiratory effects seen during different intra-abdominal pressures in the supine state are summarized in Table 10-2. It is of note that these physiologic parameters may be further altered (i.e., overridden or reversed) owing to the health of the individual patient and to changes in the patient's position.

Cardiovascular Effects of the Pneumoperitoneum

Venous Flow

Animal studies have shown that the effects of the pneumoperitoneum on venous return depend on atrial pressures, which, in turn, are a reflection of the hydration state of the subject (Ivankovich et al, 1975; Diamant et al, 1978; Kashtan et al, 1981). If atrial pressures are low (normal or hypovolemic state), then, during a pneumoperitoneum of up to 20 mm Hg, venous return is reduced owing to increased compression of the vena cava from the pneumoperitoneum. If atrial pressures are high (hypervolemic state), the vena cava resists elevated intra-abdominal pressure and venous return is actually enhanced. However, these principles apply only to an intra-abdominal pressure of up to 20 mm Hg. By further increasing pneumoperitoneum pressures, especially to 40 mm Hg and above, capacitance vessels are collapsed, vascular resistance increases, blood flow decreases markedly, and venous return is significantly reduced. Lower extremity venous return is also reduced by elevated intra-abdominal pressures. Reduced venous blood flow in the lower extremities could facilitate deep vein thrombosis; however, this remains a rare clinical complication of laparoscopy (Jorgensen et al, 1993).

These pathophysiologic insights, gained through animal experiments, have been corroborated by clinical studies (Kelman et al, 1972; Motew et al, 1973; Lee, 1975; Jorgensen et al, 1993). As a result of these trials, intra-abdominal pressures during laparoscopy should not be allowed to exceed 20 mm Hg over extended periods (Arthur, 1970; Seed et al, 1970; Lee, 1975), and a working pressure of 10 to 12 mm Hg is recommended.

Cardiac Arrhythmias

Tachycardia and ventricular extrasystoles may be seen as results of hypercapnia (Scott and Julian, 1972). Peritoneal irritation may lead to vagal stimulation and subsequently to bradyarrhythmias (Doyle and Mark, 1989). Also, dysrhythmias can serve as clinical warning signs for the occurrence of pneumothorax, hypoxia, and gas embolism (Wolf and Stoller, 1994).

TABLE 10-2 Pressure Effects: 5, 10, 20, and 40 mm Hg

EFFECTS	5 mm Hg	10 mm Hg	20 mm Hg	40 mm Hg
CARDIOVASCULAR				
Heart rate	↑	↑	↑	↓
Mean arterial pressure	↑	↑	↑	↑
Systemic vascular resistance	↑	↑	↑	↑
Venous return	→/↓	↓ ↑	↓ ↑	↓
Cardiac output	→/↓	→/↑	→/↓	↓
RENAL				
Glomerular filtration rate	→	↓	↓ ↓	↓ ↓
Urine output	→	↓	↓ ↓	↓ ↓
RESPIRATORY				
End-tidal CO ₂	→	→/↑	→/↑	↑
PCO ₂	→	↑	↑	↑
Arterial pH	→	→/↓	↓	↓

CO₂, carbon dioxide; PCO₂, partial pressure of carbon dioxide.

Unreliability of Central Venous Pressure Readings

As previously noted, intravenous pressures may actually rise with low intra-abdominal pressures. In addition, increasing intra-abdominal pressures may artificially elevate central venous pressure readings owing to an increase in intrathoracic pressure. Therefore, it is important for the anesthetist *not* to rely on central venous pressure readings for any clinical decision making.

Respiratory Effects of the Pneumoperitoneum

Pressure-Mediated Effects

Owing to increased intra-abdominal pressure, diaphragmatic motion is limited. Pulmonary dead space remains unchanged, but functional reserve capacity decreases (Wolf and Stoller, 1994). The average peak airway pressure needed to keep up a constant tidal volume increases parallel to the increasing intra-abdominal pressure (Alexander et al, 1969; Motew et al, 1973; Wolf and Stoller, 1994).

Although usually not of great clinical importance in a healthy patient population, it is advisable to use positive end-expiratory pressure techniques when patients with lung disease undergo general anesthesia for a laparoscopic procedure (Ekman et al, 1988; Wolf and Stoller, 1994; Hazebroek et al, 2002).

Non-Pressure-Related Respiratory Effects

The head-down position, commonly used in laparoscopic procedures, has an adverse effect on respiration. It elevates the diaphragm and decreases vital capacity. It can also lead to a dislocation of the endotracheal tube that, in turn, may cause right main bronchus intubation. Although of little clinical significance in healthy patients, the head-down position may cause pulmonary edema in patients with increased left-sided heart pressures (Prentice and Martin, 1987). Also, during lengthy procedures performed with the patient in the head-down position, it is useful to limit fluid administration if possible because it will minimize facial swelling postoperatively.

Renal Effects of the Pneumoperitoneum

Increased intra-abdominal pressure was found to be associated with a significant decrease in urinary output. A number of investigators, with the oldest study dating back to 1923, have observed **oliguria** and anuria associated with an ongoing increase in intra-abdominal pressure (Thorington and Schmidt, 1923; Harmann

et al, 1982; Richards et al, 1983). Decreased renal vein blood flow and direct renal parenchymal compression, rather than marked hormonal changes or ureteral compression, have been shown to be the likely reasons for the oliguric state (Chiu et al, 1994; McDougall et al, 1996). Of interest, renal cortical blood flow decreases with increasing intra-abdominal pressures, whereas renal medullary blood flow increases up to pressures of 20 mm Hg; above this level, medullary blood flow also decreases (Chiu et al, 1994).

In general, if one desires to avoid an oliguric state during a laparoscopic procedure, a pressure of 10 mm Hg or less is recommended. In addition, clinically the use of furosemide (Lasix), mannitol (12.5 to 25 g), and dopamine at 2 µg/kg/min can help to overcome oliguria. With this regimen and judicious fluid administration, the patient can usually be maintained with a urine output in excess of 100 mL/hr. The key is to use these pharmaceutical modalities in lieu of excessive hydration and fluid boluses (Perez et al, 2002), which may lead to significant fluid overload and edema.

Effects of the Pneumoperitoneum on Mesenteric Blood Flow and Intestinal Motility

Decreased blood flow during laparoscopic procedures was found not only in the kidney, but also in mesenteric vessels and other organs (e.g., liver, pancreas, stomach, spleen, small and large intestines) (Caldwell and Ricotta, 1987; Ishizaki et al, 1993; Hashikura et al, 1994). This may rarely lead to mesenteric thrombosis with catastrophic results. This complication may take days to develop (Schorr, 1998).

Open, incisional abdominal surgery usually results in some postoperative impairment of gastric and intestinal emptying owing to intestinal paralysis (physiologic ileus) (Kemen et al, 1991). It is interesting to note that clinical observation and studies undertaken during laparoscopic and open surgical cholecystectomy have shown that laparoscopic surgery causes less significant disturbances of the gastrointestinal motility pattern, therefore resulting in no or less postoperative physiologic ileus than occurs with open surgery (Sezeur et al, 1993; Halevy et al, 1994). The exact mechanisms responsible for this difference have yet to be defined; however, it is postulated that perhaps it is related to the hypercarbia (Aneman et al, 2000). In addition, intestinal perfusion does not change significantly during prolonged pneumoperitoneum at a pressure of 15 mm Hg with CO₂ or helium (Goitein et al, 2005); however, at least in the rat model, there does seem to be an increase in bacterial translocation that is proportional to the pneumoperitoneum pressure (Sukhotnik et al, 2006).

Also, despite the increased intra-abdominal pressures associated with laparoscopy, there has been no increased incidence of gastroesophageal reflux and regurgitation in patients undergoing laparoscopic procedures (Schippers et al, 1992).

Acid-Base Metabolic Effects of Pneumoperitoneum

Animal and human studies have demonstrated that prolonged laparoscopic procedures may result in hypercarbia and respiratory acidosis (Motew et al, 1973). Because there is no increase in ventilatory dead space during laparoscopy, the resulting respiratory acidosis has been attributed to transperitoneal absorption of CO₂ during establishment and maintenance of the pneumoperitoneum (Motew et al, 1973; Leighton et al, 1993). Although the resulting mild respiratory acidosis does not adversely affect otherwise normal patients and can be corrected by increasing the minute ventilation, increased absorption of CO₂ can become dangerous in patients with COPD owing to their impaired ability to release pulmonary CO₂. To ensure proper monitoring of acid-base status, intermittent arterial blood gas sampling should be performed in patients with COPD, during any laparoscopic procedure that requires more than 1 hour of CO₂ insufflation; also in patients with COPD, arterial blood gas sampling should continue in the postanesthesia recovery area because after extubation these patients may be at risk of significant hypercarbia owing to subsequent mobilization of procedurally absorbed CO₂.

The potential for developing hypercarbia exists during both transperitoneal and preperitoneal laparoscopy. Carbon dioxide is absorbed from the peritoneal membrane during transperitoneal laparoscopy and from preperitoneal adipose and connective tissue during retroperitoneoscopy and extraperitoneoscopy (Collins, 1981). Others have also implicated the disrupted microvascular and lymphatic channels for CO₂ absorption during preperitoneal laparoscopy (Glascok et al, 1996). Several studies have demonstrated that CO₂ absorption during either transperitoneal or retroperitoneal laparoscopy increases significantly during the initial 30 to 60 minutes of the procedure and reaches a steady-state plateau thereafter (Wolf et al, 1995; Ng et al, 1999). Which one of the two approaches is associated with greater CO₂ absorption remains a debated issue. Although some studies have demonstrated greater absorption during transperitoneal laparoscopy (Giebler et al, 1997), others have demonstrated greater absorption during retroperitoneal laparoscopy using a standard Hasson cannula (Wolf et al, 1995). However, in another study, no significant clinical difference was seen (Ng et al, 1999), provided a balloon tip-type cannula was used that tightly sealed the site of entry between the balloon and soft cuff carried on the shaft of the cannula.

Although transperitoneal and retroperitoneoscopic approaches are routinely used safely at numerous centers worldwide, vigilant perioperative anesthetic management is essential to prevent the development of potential complications related to CO₂ buildup, particularly in patients with preexisting airway and cardiovascular compromise. End-tidal CO₂ and O₂ saturation should be monitored intraoperatively with a capnometer. Furthermore, arterial blood gases are obtained during prolonged laparoscopic procedures and in patients with increased risk of developing hypercarbia (owing to airway disease, renal failure, congestive heart failure, or advanced age). A rise in end-tidal CO₂ should prompt the anesthesiologist to adjust the respiratory rate and tidal volume to enhance CO₂ elimination. Simultaneously, the surgeon should decrease the insufflation pressure of CO₂ or, if necessary, desufflate the abdomen until the hypercarbia has resolved.

Hemodynamic Effects Related to Patient Position and Type of Approach

Several animal and human studies have examined hemodynamic changes resulting from different surgical positions during laparoscopy (Kelman et al, 1972; Joris et al, 1993; Williams and Murr,

1993). In the supine position, cardiac output remains unchanged or decreases when intra-abdominal pressures are less than 15 mm Hg, whereas mean arterial pressure (MAP) and systemic vascular resistance increase (Pearle, 1996). If pneumoperitoneum pressures are increased beyond 20 mm Hg, cardiac output is reduced because of decreasing venous return and hence MAP decreases. Alternatively, in the head-up position, heart rate increases, MAP decreases, systemic vascular resistance increases, and cardiac output decreases. In the head-down position, heart rate drops, MAP rises, systemic vascular resistance falls, and cardiac output increases (Pearle, 1996). These results have also been shown to hold true in steep Trendelenburg position used for laparoscopic and robotic radical prostatectomy (Falabella et al, 2007). The head-down position seems to be favorable for the laparoscopy patient owing to higher cardiac output caused by increased venous return.

There is some evidence that the extraperitoneal approach may be beneficial with regard to hemodynamic effects compared with transperitoneal laparoscopy. Giebler and coworkers (1997) demonstrated that transperitoneal laparoscopy was associated with more pronounced changes in cardiac output ($P = .001$), pulmonary artery pressure ($P = .007$), central venous pressure ($P = .001$), iliac venous pressure ($P = .001$), and inferior vena caval pressure gradient ($P = .00001$) as compared with retroperitoneal laparoscopy. With regard to pelvic laparoscopy, Meininger and associates (2004) compared the effects of prolonged intraperitoneal and extraperitoneal CO₂ insufflation on hemodynamics and gas exchange. With both insufflation methods, arterial CO₂ pressure increased rapidly, reaching higher levels with extraperitoneal insufflation. Therefore patients managed with extraperitoneal insufflation required significantly higher minute ventilation. Heart rate and central venous pressure increased in both groups, whereas mean arterial blood pressure and pH decreased in both groups.

Hormonal and Metabolic Effects during Laparoscopic Surgery

As in other surgical procedures, several hormones (e.g., β -endorphin, cortisol, prolactin, epinephrine, norepinephrine, dopamine) have been noted to increase during laparoscopic surgery as a response to tissue manipulation, intraoperative trauma, and postoperative pain (Cooper et al, 1982; Lehtinen et al, 1987; Lefebvre et al, 1992). The clinical significance of increased serum arginine vasopressin levels seen in open surgery and in response to intraperitoneal insufflation during laparoscopy remains unexplained (Cochrane et al, 1981; Melville et al, 1985; Solis Herruzo et al, 1989).

Several adverse metabolic changes observed during open cholecystectomy are less pronounced with laparoscopic cholecystectomy: (1) reduced postoperative plasma glucose elevation, (2) less decrease in insulin sensitivity, and (3) reduced hepatic stress response (Thorell et al, 1993; Jakeways et al, 1994; Glerup et al, 1995).

One important feature of the catabolic response is a complex intra-organ shift of nitrogen; this reaction has been best characterized in the liver (Glerup et al, 1995). The conversion of amino acids to urea by the liver is much higher after open cholecystectomy than it is after laparoscopic cholecystectomy. Hence, the catabolic reaction of the body is decreased with a laparoscopic versus an open approach (Fischer, 1995). Indeed, in the laparoscopic patient, the reduced postoperative hepatic catabolic stress associated with reduced tissue loss of amino-nitrogen may, in some way, be responsible for the more rapid convalescence that is the hallmark of laparoscopy in general. Lastly, catabolic responses, in the form of released cytokines and opioids, resulting from augmented neurohumoral stimuli caused by incisional tissue trauma may also be lessened with a laparoscopic approach (Fischer, 1995).

Immunologic Effects of Laparoscopic Surgery

A number of animal and clinical studies measuring a wide spectrum of inflammatory response mediators (e.g., C-reactive protein,

interleukin-6) and other markers of cellular immune functions (pan-T cells [CD3], helper T cells [CD4], suppressor cells [CD8], and natural killer cells [CD16]); delayed-type hypersensitivity skin tests; serial phytohemagglutinin-induced T-cell proliferation) have suggested that laparoscopic procedures in general result in less immunosuppression than do their open counterparts (Kloosterman et al, 1994; Trokel et al, 1994; Cristaldi et al, 1997; Karayiannakis et al, 1997; Nguyen et al, 1999; Bolla and Tuzzato, 2003). This may also play a role in hastening convalescence after laparoscopic procedures. Some data have suggested that the CO₂ pneumoperitoneum in and of itself, as opposed to exposure of tissues to room air, results in a more favorable immunologic state (Watson et al, 1995). Also, experimental evidence shows that less tumor cell growth occurs after laparoscopic procedures than after open procedures (Bouvy et al, 1997). Although these data are intriguing, further well-designed, prospectively randomized clinical studies are needed to compare immunologic responses after laparoscopic versus open surgical procedures for urologic cancer. Indeed, in a study by Landman and colleagues (2004) there was no discernible difference in immunologic parameters between patients undergoing open or transperitoneal laparoscopic radical or total nephrectomy for renal cancer. Ultimately, whether a decrease in inflammatory response mediators and improved postlaparoscopic immune status will translate into a better long-term prognosis for patients with urologic cancers remains to be determined.

KEY POINTS: PHYSIOLOGIC CONSIDERATIONS IN THE ADULT

- Carbon dioxide is the most commonly used insufflant because it is noncombustible and rapidly absorbed in the blood.
- Helium is particularly useful for the patient with pulmonary disease in whom hypercarbia would be poorly tolerated.
- Intra-abdominal pressures during laparoscopy should not be allowed to exceed 20 mm Hg over extended periods, and a working pressure of 10 to 12 mm Hg is recommended.

COMPLICATIONS AND TROUBLESHOOTING IN LAPAROSCOPIC AND ROBOTIC SURGERY

Historically, in large series the overall incidence of laparoscopic complications in urology has been in the range of 4% and mortality has been distinctly unusual, with a rate of 0.03% to 0.08% (Mintz 1977; Winfield et al, 1991; Fahlenkamp et al, 1999). More contemporary series demonstrate a complication rate in the range of 13% to 22% (Table 10-3) (Vallancien et al, 2002; Parsons et al,

2004; Permpongkosol et al, 2007), likely representative of the introduction of new, more sophisticated laparoscopic procedures and more widespread use of laparoscopy. Vascular followed by adjacent organ injuries are the most common complications (Permpongkosol et al, 2007; Breda et al, 2009). The following section covers the myriad complications that can occur with any laparoscopic or robotic procedure. Recognition, resolution, and prevention of these various problems are discussed.

Minimizing the Incidence of Complications during the Learning Curve

Early in one's experience with laparoscopic and robotic surgery, it is wise to first apply this approach to low-risk surgical candidates of normal body habitus. In addition, it is advisable and recommended by many laparoscopic organizations, as well as by hospital credentialing boards, that the neophyte minimally invasive surgeon seek training in three arenas: (1) in-depth instructional courses, including didactic, "live-case" transmissions and "hands-on" laboratory sessions; (2) preceptor training in which the surgeon-in-training views five or more procedures being done by an already skillful laparoscopic or robotic surgeon; and (3) a mentoring experience, during which a trained laparoscopic or robotic surgeon oversees the initial procedures performed by the surgeon-in-training (Society of American Gastrointestinal and Endoscopic Surgeons, 2010). Further training can be obtained through self-teaching using videotapes, a laparoscopic box trainer, and virtual reality (VR) simulators. A laparoscopic box trainer is extremely helpful for developing one's sense of laparoscopic proprioception and for becoming facile with laparoscopic suturing and knot tying. Data have clearly shown benefits for individuals who have taken the time to practice their laparoscopic skills using a box trainer in all areas of laparoscopy (cutting, clipping, and suturing) compared with individuals who had no such training (Derossis et al, 1998). Similarly, participation in a 1-week mini-residency has been found to increase the likelihood that participants would perform more complex laparoscopic procedures (81% of participants) (Corica et al, 2006). In addition, VR simulators have been shown to improve the operative performance of surgical trainees with limited laparoscopic experience when compared with no training or with box-trainer training (Nagendran et al, 2013).

Aside from training in the basic psychomotor skills, neophyte minimally invasive surgeons must be educated with regard to prevention, recognition, and appropriate treatment of complications.

General Procedural Complications

Malfunction of Equipment

A successful outcome of any laparoscopic or robotic procedure depends not only on the psychomotor technical skills of the surgeon, but also on a proper working knowledge of all the equipment involved in performing these procedures. To ensure undisturbed functioning of all technology, the surgeon must be supported by well-trained staff who are capable not only of quickly recognizing any equipment malfunction, but also of providing an immediate, adequate response to correct problems. In this regard, the Society of American Gastrointestinal Endoscopic Surgeons has issued a troubleshooting guide for video and electronic failure. For integrated operating room systems offered by most major equipment manufacturers and the da Vinci Robotic System, the surgeon and operating room staff need to receive in-depth training on the system's operation, capabilities, and limitations. In this way, equipment failure will be minimized. In addition, the contact information for both the equipment vendor's troubleshooting experts and any in-house support should be readily available.

With regard to the da Vinci Robotic System, equipment malfunction is rare. In a review of 11 institutions with a total of 8240 cases reviewed, the overall incidence of malfunction was 0.4%. Of the 34 cases with malfunction, 24 cases were canceled before the

procedure, 2 cases were converted to laparoscopic procedures, and 8 were converted to open surgery (Lavery et al, 2008).

Complications Related to Obtaining the Pneumoperitoneum

Complications Associated with Closed Access (Veress Needle Placement)

Preperitoneal Placement. Preperitoneal placement of the Veress needle may preclude successful trocar placement. If not recognized early, 1 to 2 L of CO₂ may be instilled, and once this much CO₂ has been insufflated into the preperitoneal space, many signs indicative of correct intraperitoneal insufflation may be present (e.g., distention, tympanic sound on percussion) thereby misleading the surgeon until the first trocar is placed. **The first sign of preperitoneal insufflation is that there may be a steep rise in pressure with only 500 mL of CO₂; plus, if more CO₂ is instilled, unequal distention of the abdomen occurs.** If this early sign is missed, then the laparoscope reveals only fat after trocar placement; the intraperitoneal viscera are not seen.

The next step is to evacuate the CO₂ through the sidearm of the trocar and proceed with an open insertion technique. The initial incision can be widened, and the peritoneal surface can be grasped with a pair of Allis clamps and incised. A Hasson cannula is placed and the peritoneal cavity is insufflated.

Several steps can be taken to avoid this complication. First, if the Veress needle is preperitoneal on initial insufflation, pressures are usually higher than the maximal initial allowable pressure of 10 mm. Second, if the Veress needle is preperitoneal, it cannot be easily advanced 1 cm deeper without resistance. If one has truly entered the peritoneal cavity properly, the Veress needle should be able to be moved 0.5 to 1 cm deeper without meeting any resistance.

Vascular Injuries. During initial placement of the Veress needle at the umbilicus, minor or major intra-abdominal blood vessels may be punctured by the 14-gauge needle. The first sign of intravascular entry is blood appearing in the hub of the needle. Aspiration results in additional blood filling the syringe. As long as the needle has not been manipulated, it can usually be withdrawn without excessive bleeding. An alternative site for Veress needle placement or open cannula insertion should be used at this point. On proper entry into the peritoneal cavity and establishment of a pneumoperitoneum, it is important that the path of the initial Veress needle passage be traced. The prior site of the Veress needle passage should be carefully inspected at a pressure of 5 mm Hg. Any site of bleeding can be expeditiously treated by applying gentle pressure and the application of a surgical hemostatic agent as needed.

To prevent this problem it is important when using an umbilical approach to direct the Veress needle toward the pelvis. One technique to help prevent this problem, when using an umbilical access, is to pass the Veress needle after making a 12-mm incision, bluntly spreading the subcutaneous fat, and grasping and stabilizing the anterior fascia with a pair of Allis clamps. These maneuvers become especially important in children, who have less space between intra-abdominal structures and the abdominal wall.

Surgeons should also be cognizant that any hemodynamic instability associated with loss of "working space" within the abdomen during the procedure might represent an expanding "unseen" retroperitoneal hematoma from unrecognized Veress needle injury.

Prevention of vascular complications can be further achieved by using a nonumbilical site for Veress needle passage (i.e., just superior and medial to the iliac crest or subcostal in the midclavicular line) where no major vessels are placed in danger.

Visceral Injuries. During Veress needle placement, intra-abdominal organs may be punctured. The initial signs of this complication consist of aspiration of blood, urine, or bowel contents through the Veress needle or, in the case of a solid organ, high pressures on initial insufflation.

Management consists of simply removing the Veress needle. The Veress needle may then be reintroduced at a different site, or an open Hasson technique can be used through a separate incision site. On entry into the abdomen, any bleeding site on the liver or spleen

can be treated with gentle pressure, an argon beam coagulator, or the application of a surgical hemostatic agent as needed. General surgical consultation should be sought in those cases in which there is difficulty achieving hemostasis.

Bowel or bladder entry by the Veress needle needs no further treatment other than needle withdrawal. Placing a nasogastric tube and a transurethral indwelling bladder catheter to decompress the stomach and bladder, respectively, before Veress needle passage can help to prevent these problems.

Complications during Open Access (Hasson Technique). Potential problems associated with open access are similar to, albeit less frequent than, problems associated with a closed Veress needle access. The principal risk with the open access is injury to underlying viscera while traversing the peritoneum. In a densely scarred abdomen, the bowel may be adherent to the underside of the abdominal wall and hence may still be injured. If a bowel injury is recognized early, it can often be repaired through the same incision that was made for insertion of the Hasson cannula. Although vascular injury with this approach is distinctly rare, the surgeon must realize that even with open access this devastating complication can occur (Hanney et al, 1999).

Complications Related to Insufflation and Pneumoperitoneum

Bowel Insufflation. If entry into the bowel is not recognized at the time of irrigation and aspiration through the Veress needle, then the surgeon may well insufflate the small or large bowel. **The first sign of this problem is asymmetrical abdominal distention followed by flatus and insufflation of only a small amount of CO₂ (<2 L) before high pressures are reached.**

If this complication is suspected, then the insufflation line should be disconnected; the outflow of gas will immediately confirm bowel entry. The needle can be withdrawn, and open access cannula placement should be done at a different abdominal site. Prevention of this problem is ensured if one properly performs the aspiration, irrigation, and aspiration tests recommended for safe Veress needle placement and if one avoids sites of prior surgery. Alternatively, initial use of open access technique should avoid this complication.

Gas Embolism. Carbon dioxide gas has favorable solubility in blood, as opposed to air, helium, or nitrous oxide; however, use of CO₂ may still result in a gas embolus. The most common cause of CO₂ embolism is puncture of a blood vessel or organ with the Veress needle, followed by insufflation; this can occur only when the surgeon has ignored the previously described tests for proper entry into the peritoneal cavity. The first sign of intravascular insufflation is acute cardiovascular collapse. Other signs include dysrhythmias, tachycardia, cyanosis, and pulmonary edema. **The dysrhythmias is usually made by the anesthesiologist based on an abrupt increase of end-tidal CO₂ accompanied by a sudden decline in oxygen saturation and then a marked decrease in end-tidal CO₂ (Loris, 1994).** Sometimes, a "millwheel" precordial murmur can be auscultated (Keith et al, 1974). In addition, the anesthesiologist may notice foaming of a blood sample, if drawn, as a result of the presence of insufflated CO₂.

The treatment is immediate cessation of insufflation and prompt desufflation of the peritoneal cavity. The patient, if at all possible, is turned to a left lateral decubitus (i.e., right side up), head-down position in hopes of minimizing right ventricular outflow problems and forcing the air embolus to rise into the apex of the right ventricle. The patient is hyperventilated with 100% oxygen. Advancement of a central venous line into the right side of the heart with subsequent attempts to aspirate gas may rarely be helpful. The use of hyperbaric oxygen and cardiopulmonary bypass have also been reported (McGrath et al, 1989; Diakun, 1991; Abdel-Meguid and Gomella, 1996).

This devastating complication can be precluded by meticulous attention to Veress needle and initial trocar placement and performance of each of the recommended tests for intraperitoneal

entry. Insufflation should never be initiated if the surgeon has even the slightest doubt about correct positioning of the Veress needle; instead, the surgeon should withdraw the Veress needle and pass it at an alternate site or should immediately proceed with open access.

Barotrauma. Prolonged elevated pressures (>15 mm Hg) may result in barotrauma (McGrath et al, 1989; Diakun, 1991; Abdel-Meguid and Gomella, 1996). Prolonged high pressures may be caused by insufficient and infrequent monitoring of CO₂ pressure, malfunction of the insufflator, or additional pressures produced by auxiliary devices (e.g., argon beam coagulator, CO₂-cooled laser). Furthermore, barotrauma may be caused by ventilation techniques using positive end-expiratory pressure resulting in rupture of a pulmonary bleb or bulla.

The initial sign of barotrauma may be hypotension caused by decreased cardiac output, secondary to an acute drop in venous return caused by compression of the vena cava. Also, a pneumothorax or pneumomediastinum may develop because of the high ventilation pressures. In addition, increased intra-abdominal pressures may exacerbate a hiatal hernia.

The anesthesiologist, who will notice an increase in ventilation pressures, usually alerts the surgeon to excessive intra-abdominal pressure. The surgeon should desufflate the abdomen and, once the hemodynamic changes have been reversed, reinitiate the pneumoperitoneum at 10 mm Hg. Any malfunctioning insufflator should be replaced. Also, if one is using an argon beam coagulator or a CO₂-cooled laser device, the sidearm on one port should be left open to allow excess high-pressure gas to escape while the device is being activated.

Barotrauma secondary to insufflator malfunction can be avoided by routinely troubleshooting the insufflator before every case.

Subcutaneous Emphysema. Subcutaneous emphysema develops owing to improper placement of the Veress needle or, more commonly, to leakage of CO₂ around ports. The latter situation occurs when a secure seal around the Hasson cannula is not obtained, port site incisions are too large, the procedure is particularly lengthy, or high intra-abdominal pressures are used. The pathognomonic sign is crepitus over the abdomen and thorax; in male patients, a pneumoscrotum may also develop.

If the problem is caused by improper placement of the Veress needle, then withdrawal of the Veress needle and use of the open technique are recommended. If the problem develops intraoperatively, the surgeon should check for gas leakage around a port site, including the Hasson cannula if the open technique was used. If leakage is found, the surgeon can either place a purse-string suture around the port or, preferably, change the trocar to a larger size or switch to a balloon trocar, which creates a tight seal between the intra-abdominal balloon and outer cuff. Also, the surgeon should consider reducing the insufflation pressure. This complication is eminently avoidable if the surgeon adheres to all the diagnostic tests for proper Veress needle placement and ensures all port site incisions are carefully tapered to the size of the port to be placed. In this regard, it is important to place each port so that it is pointing toward the surgical field, to avoid the continued forceful redirection of the port during the procedure that results in widening of the tissue tract around the port and subsequent escape of CO₂ into the surrounding subcutaneous tissues.

Several studies have demonstrated that the incidence of subcutaneous emphysema is higher during retroperitoneal laparoscopy than during transperitoneal laparoscopy, albeit without any clinically significant sequelae (Wolf et al, 1995; Zhao et al, 2008). In any event, the risk of surgical emphysema and other CO₂-related sequelae during retroperitoneoscopic and extraperitoneoscopic surgery can be effectively minimized by working at a lower pressure (i.e., 12 mm Hg vs. 15 mm Hg) (Rassweiler et al, 1998a) and using a balloon trocar to seal the initial entry site (Gill, 1998; Ng et al, 1999).

Pneumomediastinum, Pneumothorax, and Pneumopericardium. Gas leaking along major blood vessels through congenital defects or secondary enlargement of openings in the diaphragm may lead to pneumomediastinum, pneumopericardium, or

pneumothorax (Kalhan et al, 1990; Pascual et al, 1990; See et al, 1993; Abreu et al, 2004; Zhao et al, 2008). Although a pneumomediastinum is usually not associated with specific clinical symptoms, a pneumopericardium may result in impaired cardiac function. The incidence of the pneumopericardium is estimated to be 0.8% (Abreu et al, 2004). The diagnosis is usually made on a chest radiograph taken in the recovery room, except in rare instances when cardiac impairment occurs during the procedure. If there is sudden cardiac decompensation during a procedure, the same maneuvers should be undertaken as described for treatment of a suspected gas embolism, including interruption of the procedure and desufflation of the abdomen. If there is a strong suspicion of pericardial tamponade, pericardiocentesis is indicated.

A pneumothorax may be associated with pneumomediastinum, barotrauma, or direct puncture of the pleural space with a trocar (Doctor and Hussain, 1973; Kalhan et al, 1990; Pascual et al, 1990). The incidence of this complication has been found to be 1.6% to 4.0% (Abreu et al, 2004; Zhao et al, 2008). Like subcutaneous emphysema, the incidence of pneumothorax is more common in retroperitoneal procedures (Zhao et al, 2008). The earliest signs of this problem may be the development of subcutaneous emphysema, especially in the neck and chest area. More ominous signs, such as hypotension and decreased breath sounds with an increase in ventilatory pressure, are indicative of a tension pneumothorax. Although a chest radiograph will confirm the diagnosis, the development of pulmonary collapse with loss of breath sounds on one side mandates immediate decompression of the chest by passage of a 16-gauge needle into the second or third intercostal space in the midclavicular line followed by tube thoracostomy, if a tension pneumothorax is suspected (See et al, 1993).

Prevention of these problems is similar to the means to avoid subcutaneous emphysema: Keep the intra-abdominal pressure preferably at 12 mm Hg, make sure all port site incisions are tight around the laparoscopic cannulae, and make sure all cannulae are well seated in the peritoneal cavity. In addition, all trocars must remain below the 12th rib. While dissecting in the upper quadrants of the abdomen, especially during laparoscopic ablative renal surgery, the surgeon should be aware of the anatomic relationships of the kidneys, adrenal glands, and great vessels to the diaphragm to avoid direct injury.

Complications Related to Initial “Blind” Placement of the First Trocar after Obtaining a Veress Needle Pneumoperitoneum

With the advent of nonbladed trocars (several of which also have clear tips for direct visualization of individual abdominal wall layers during port placement), the likelihood of catastrophic injuries to vital structures has been markedly reduced (Thomas et al, 2003).

Injury to Gastrointestinal Organs. Perforation of the small or large intestine during passage of the primary port is the most common cause of trocar-induced injury of gastrointestinal organs. Other organs (e.g., stomach) are affected much less frequently. Given the lateral positioning of the spleen and liver, injury of these organs with the passage of the primary trocar is distinctly unusual. The first sign that one has entered the bowel depends on whether the injury is through one wall or both walls of the bowel. In the former instance, as soon as the laparoscope is introduced the surgeon sees the mucosal folds of the interior of the bowel. However, with a through-and-through injury the diagnosis is not made until the first secondary trocar is passed; **at that time the surgeon should routinely pass the laparoscope through the secondary port to inspect the puncture site of the initial port.** The trocar will be seen passing completely through both walls of the bowel. If the surgeon fails to perform this maneuver routinely this injury will not be noted until the end of the case when the trocars are being removed, thereby resulting in a broader injury and a prolonged time of intraperitoneal contamination. A missed bowel injury of this nature leads to peritonitis when diagnosed intraoperatively, and possible death when discovered only in the postoperative period.

In the case of a one-wall injury of the bowel, the surgeon can elect to leave the trocar in place and pass a second trocar in another location using an open access technique. On inspection of the abdomen the site of injury to the bowel will be immediately apparent because the initial trocar will still be residing in the bowel. At this time, the surgeon may elect to open and repair the bowel or, if skilled in laparoscopy, may place two more ports and proceed to close the bowel using laparoscopic suturing or stapling techniques. An intraoperative consultation with a general surgeon should be obtained regardless of whether the urologist performs the repair; from a medicolegal and quality of care standpoint, involvement of the general surgeon at the time of the acute event facilitates subsequent care should further complications arise while ensuring the best possible repair of the injury at the time of the acute event.

When the injury to the bowel is a through-and-through injury, it can similarly be repaired with an open or laparoscopic approach. In either case, the abdomen should be irrigated with 4 to 5 L of saline containing an antibiotic solution, and the patient must be placed on broad-spectrum antibiotic coverage.

Perforation of the stomach is distinctly rare; however, to best preclude this problem patients should refrain from oral intake for 12 hours before surgery. The management of this complication is the same as for injury to the bowel, with primary closure and general surgery consultation. In addition, when the stomach is noted to be distended, a nasogastric or orogastric tube should be placed to decompress the stomach and facilitate further trocar insertion.

Injury to Intra-Abdominal Vessels. Major vascular injury is a rare but serious complication, occurring in 0.11% to 2% of cases (Hanney et al, 1995; Geers and Holden, 1996; Usal et al, 1998; Lin and Grow, 1999; Vallancien et al, 2002; Parsons et al, 2004). It is far more common in procedures related to the retroperitoneum, as opposed to pelvic laparoscopy. The aorta and common iliac arteries are most frequently involved. The inferior vena cava is less affected because of its lateral location in relation to the aorta; likewise, the common iliac vein is rarely involved given its posterior position in relation to the common iliac artery. Rarely, in a patient with adhesions or prior surgery, intestinal mesenteric vessels servicing a "fixed" loop of bowel may be injured. In addition, the epigastric vessels are at risk for injury during trocar placement.

The first sign of a major vascular complication is the onset of sudden hypotension and associated tachycardia. If the trocar has not been moved, then, as the obturator is withdrawn, the diagnosis is made immediately based on whether there is a pulsatile (arterial) or nonpulsatile (venous) profuse bleeding from the trocar sheath. If the trocar has been displaced from the injured vessel, then, depending on the vessel injured, when the laparoscope is introduced the surgeon will see blood rapidly accumulating in the abdominal cavity, a mesenteric hematoma, blood dripping from the trocar entry site, or, rarely, blood that preferentially accumulates retroperitoneally, in which case the space within the peritoneal cavity will appear to be markedly reduced and actively decreasing because of the expanding retroperitoneal hematoma.

The response to injury to a major arterial or venous structure must be rapid. A vascular or trauma surgeon should be called to the room. If blood is coming through the trocar, then the trocar should be closed and left in place. An emergency laparotomy is performed, and the trocar is followed to its point of entry into the vessel. The injured vessel should be controlled proximal and distal to the site of trocar injury with vessel loops or bulldog clamps, or alternatively a Satinsky clamp can be placed to isolate the area of injury so that as the trocar is withdrawn the wound can be controlled and repaired quickly. If the injury is discovered at the time of passage of the laparoscope (i.e., the trocar is no longer residing in the vessel), then the sheath and laparoscope can be swung up to the underside of the abdominal wall and an immediate cutdown can be done on top of the laparoscope and sheath, thereby providing for a rapid and safe laparotomy. Alternatively in this situation, the procedure can be converted to a hand-assist approach and the surgeon can then use the intra-abdominal hand to control the bleeding vessel.

BOX 10-3 Contents of Hemorrhage Tray for Laparoscopic Surgery

Laparoscopic Satinsky clamp
Ten-millimeter suction-irrigation tip
Endo Stitch device with 4-0 absorbable suture
Lapra-Ty clip applier and a packet of Lapra-Ty clips
Six-inch length of 4-0 vascular suture on an SH needle with a Lapra-Ty clip preplaced on the end
Two laparoscopic needle drivers
Topical hemostatic agent of choice

The best way to handle this complication is to avoid it completely. In this regard, knowledge of the exact location and possible anatomic variations of major intra-abdominal blood vessels is mandatory. The preoperative computed tomography (CT) scan should be reviewed before operating to look for vena caval or other abnormalities of the great vessels. Because of limited intraperitoneal space, special care must be given to trocar placement in children and very thin adults. It is important to note that several maneuvers can be used to help prevent vascular injury. These include ensuring that all the safety signs of passage of a Veress needle are present before proceeding with trocar passage, obtaining an adequate pneumoperitoneum before trocar passage (intra-abdominal pressure may be raised to 25 mm Hg temporarily for placement of the primary trocar), passing the initial trocar under direct endoscopic control (i.e., optical trocar), using blunt nonbladed trocars, and avoiding initial trocar passage through an abdominal scar.

Furthermore, it is helpful to consider having a "hemorrhage" tray available in the operating room at all times (Box 10-3). This laparoscopic tray should contain a Satinsky clamp, a 10-mm suction tip for large clot evacuation, an Endo Stitch device with 4-0 Vicryl suture, a Lapra-Ty clip applier and a rack of Lapra-Ty clips (six clips per rack), two laparoscopic needle holders, and 4-0 vascular suture. With this tray available, some injuries to major venous structures can be successfully resolved laparoscopically.

Injury to the Urinary Tract. Urinary tract injuries during laparoscopy are most commonly associated with trocar passage, specifically injury to the bladder at the time of initial trocar placement. The incidence varies widely in the gynecologic literature, ranging from 0.02% to 8.3% (Ostrzenski and Ostrzenska, 1998; Lin and Grow, 1999; Soong et al, 2007). Chances of this problem occurring have been greatly reduced by the introduction of blunt trocars.

The initial sign of this problem is pneumaturia or gross hematuria. The diagnosis can be confirmed by retrograde intravesical instillation of indigo carmine diluted with saline; this allows the surgeon to rapidly identify the cystotomy site. The injury can be repaired laparoscopically with laparoscopic suturing techniques; however, extensive defects may require open surgical repair (Ostrzenski and Ostrzenska, 1998). These injuries should always be closed and not left to heal on their own with prolonged Foley catheter drainage.

Prevention of this problem is simple. Preoperative placement of a urethral catheter to drain the bladder is recommended for all major laparoscopic urologic cases. Not only does it largely preclude bladder injury, but it also provides the necessary means for monitoring urine output during major laparoscopic procedures.

Complications Related to Placement of Secondary Trocars

Bleeding at the Sheath Site. Blood dripping from the port entry site and onto the underlying abdominal viscera is the first sign of an injured abdominal wall vessel. The exact site of hemorrhage is determined by cantilevering the trocar into each of the four quadrants and noting which position of the trocar tamponades the bleeding.

Definitive therapy for this problem can be undertaken in one of three ways. The simplest method, albeit the most costly, is the insertion of curved electrosurgical scissors or forceps through another port, which can then be articulated up into the port site to coagulate the bleeding.

The least expensive method is to suture the area of hemorrhage. This can be accomplished by inserting a straight Keith needle with a 0-0 absorbable suture from the outside of the abdomen at one side of the affected quadrant and then grasping the needle with laparoscopic forceps and pushing it back out of the abdomen at the opposite side of the affected quadrant until it can be recovered on the surface of the abdomen (Fig. 10-30). This broad suture is then tied over a gauze 4- × 4-inch bolster on the abdominal surface; the port can be used throughout the procedure. Alternatively, various port closure devices, in particular the Carter-Thomason device, may be used to similarly pass a suture to control the bleeding (Ortega, 1996). Ultimately, at the end of the procedure a device of this nature should be used to definitively close the port site and occlude the injured vessel no matter which of the aforementioned techniques is used.

This problem can often be avoided by routinely transilluminating the abdominal wall, especially in the thin patient, before trocar placement so large surface vessels and overlying peritoneal vessels can be avoided and to help identify the area of the inferior epigastric vessels. In addition, the routine spreading of the subcutaneous tissues at the proposed port site with a blunt clamp (e.g., Kelly clamp) may be helpful, and the use of only blunt trocars has been shown to reduce the chance of vascular wall injury significantly (Bhojru et al, 2000). In particular, a fivefold decrease in epigastric vessel injury has been demonstrated with blunt trocars (reduced incidence from 0.83% to 0.16%) (Hashizume and Sugimachi, 1997; Thomas et al, 2003). The incidence of any abdominal wall bleeding has also been shown to be dramatically reduced (3% vs. 9%) with blunt vs. bladed trocars

(Antoniou et al, 2013). Placing trocars either in the midline or at least 6 cm lateral to the midline has also been shown to reduce the risk of epigastric vessel injury (Hashizume and Sugimachi, 1997).

Trocar Position–Related Problems. Three potential problems may occur when the secondary trocars are not properly positioned: “crossing swords,” “striking handles,” and “rollover.” The problem of crossing swords is caused by the trocars being placed too close to one another; as a result, the intra-abdominal portions of two trocars cross each other so that the two trocars cannot be easily used to deliver instruments to the same surgical site. Similarly, the problem of striking handles is also caused by trocars being placed too close to one another. As a result, the upper portions of the trocars strike one another on the abdominal surface, again precluding delivery of instruments to a specific surgical site. Rollover is a variant of the crossing swords problem, but it occurs between the laparoscope and an instrument. Instead of running parallel to the surgical site, the primary cannula holding the laparoscope and one of the instrument-holding secondary ports are pointed toward each other. Consequently, as the instrument is advanced toward the surgical site, it strikes and is deflected by the larger laparoscope, thereby rolling over the laparoscope and hence suddenly moving out of the field of view.

By definition, these problems are more likely to occur during LESS. Because the ports are purposely placed in close proximity to one another, the surgeon must use advanced techniques or special equipment to overcome these pitfalls. This special equipment may include articulating instrumentation, instruments with different shaft lengths, and a low-profile 5-mm laparoscope.

When the da Vinci Robotic System is used, the ports should be placed at least 8 to 10 cm away from one another to avoid robotic arm collision—the robotic equivalent of striking handles. This can sometimes be challenging in thin patients with limited abdominal wall space.

Figure 10-30. A, Bleeding at the cannula site. B, Cannula can be cantilevered into each of the four different quadrants to identify the source of bleeding. C and D, Straight Keith needle may be used to traverse the site of bleeding. E, Suture is tied down over a gauze bolster. (From Clayman RV, McDougall EM, editors. *Laparoscopic urology*. St. Louis: Quality Medical Publishing; 1993.)

Usually these problems are a minor annoyance, and the surgeon and assistant need to experience the problem only once to adjust for it. To compensate for the problem of striking handles, if it should occur, the sheaths can be withdrawn a bit from the abdomen, thereby increasing the space between the handles of the instruments. The problems of crossing swords and rollover can be remedied by moving the handles of the crossing trocars closer to each other, thereby moving the tips of the trocars farther apart. When this is done to correct a rollover, the surgical site may be displaced into one corner of the monitor; however, the desired delivery of the instrument to the surgical site can then be accomplished. A 30-degree laparoscopic lens can usually allow the laparoscope to be placed parallel to the instrument it is rolling over and then rotated to maintain the operative site image and eliminate the rollover.

The best way to handle these situations is to properly place and direct each trocar at the beginning of the case, to avoid encountering these problems. For some procedures, such as pyeloplasty, this may be accomplished by placing all the trocars on the same line (i.e., midline) so they are all working parallel to one another, whereas for procedures such as nephrectomy the goal is to place the trocars so that they surround the surgical site, forming a diamond pattern within which the kidney lies. Regardless, each trocar needs to be inserted such that it points to the pathology; this precludes the problem of having to redirect the trocar throughout the case, adding to surgeon fatigue and unnecessary trauma to the peritoneum and abdominal wall musculature. **Lastly, if trocar interactions become particularly vexing during a procedure, the surgeon should not hesitate to place an additional 5-mm trocar in a more conducive site to eliminate the problem.**

Complications Related to General Anesthesia Unique to Laparoscopy

See the Expert Consult website for details.

Complications Related to the Surgical Procedure

Bowel Injury: Electrosurgical. Electrosurgically induced thermal injury may occur through one of four mechanisms: inappropriate direct activation; coupling to another instrument; capacitive coupling; and insulation failure.

Active electrode trauma by unintended activation causes direct bowel or other organ injury and may occur when the electrosurgical instrument is left unobserved within the peritoneal cavity, when it is out of the camera's view, or when someone other than the primary surgeon carries out electrode activation. Furthermore, active electrode trauma may be seen when coagulation extends beyond the intended site (thermal spread) and reaches other adjacent structures (e.g., bowel, blood vessels, ureter). This is more commonly seen when high electrocoagulation settings (i.e., >30 watts) are used.

Direct coupling may occur when the active electrosurgical instrument touches another instrument that is in direct contact with other tissue (e.g., bowel). If this happens outside the field of view of the laparoscope, it may remain unnoticed by the surgical team.

Injury caused by capacitive coupling occurs when the surrounding charge, which is intrinsic to all activated monopolar electrodes, is not allowed to conduct back to and disperse through the abdominal wall (Zucker et al, 1995; Munro, 1997). This condition may develop when a metal cannula is anchored to the skin with a nonconductive plastic grip, which, as previously noted, should never be done (Fig. 10-31). As a result, the electrical field, which builds up around the activated electrosurgical instrument and is conducted to the metal trocar through which it has been placed, cannot then be conducted to the abdominal wall because the plastic retainer acts as an insulator. This may lead to a high power density along the portion of the metal cannula that is inside the abdomen. The electrical charge built up on the cannula can then travel to other tissues in contact with the cannula. Similarly, capacitive coupling may constitute a risk when electrosurgical probes are used through operating laparoscopes, which are, in turn, inserted through plastic sheaths. The metal shaft of the laparoscope then becomes a repository for electrical current and may discharge this energy to any tissue in contact with the laparoscope. The risk of this complication is also increased when older generators with high-voltage output and/or electrodes with thicker diameters are used, especially in coagulation rather than cutting mode (Munro, 1997).

Lastly, insulation breakdown may allow current to escape along the shaft of the instrument, thereby harming tissues that are otherwise outside the field of view of the laparoscope. Insulation breakdown along the shaft of the instrument may be a result of repeated use, resterilization, or mechanical damage to the instrument during repeated insertion through a trocar. In this situation, the small

Figure 10-31. Capacitive coupling. **A**, Charge surrounding the activated monopolar electrode is conducted back to the all-metal cannula and dispersed by the abdominal wall. **B**, The electrosurgical instrument is being used through a metal cannula that has been anchored to the skin with a nonconductive plastic grip; accordingly, the electrical field cannot be conducted to the abdominal wall because the plastic retainer acts as an insulator; a stronger electrical charge is thus conducted to any other tissue in contact with the cannula.

Cardiac Arrhythmias and Cardiac Arrest. Cardiac arrhythmias can be frequently seen during anesthesia in laparoscopic procedures; the most common is sinus tachycardia. Bradyarrhythmias (e.g., atrioventricular dissociation, nodal rhythm, sinus bradycardia) may develop independently or in combination with tachycardia during the same procedure (Myles, 1991). Conditions in laparoscopy leading to development of arrhythmias include CO₂ insufflation; hypercapnia; Trendelenburg position; anesthetic drugs (especially halothane in combination with spontaneous ventilation); and gas embolism (Harris et al, 1984; Myles, 1991). In rare cases, asystolic cardiac arrest and cardiovascular collapse may develop (Shifren et al, 1992).

The role of the anesthesiologist throughout the laparoscopic procedure is of paramount importance. Continuous monitoring of cardiovascular parameters (electrocardiogram, arterial blood pressure) and pulmonary parameters (capnometry, in-line oxygen, airway pressures and tidal volume, frequent arterial blood gas analyses when indicated) is essential. Invasive cardiac monitoring should be instituted as appropriate in patients with heart disease or in high-risk patients (i.e., American Society of Anesthesiologists type 3 or 4) when prolonged and complicated laparoscopic procedures are expected.

Because hypercarbia is one of the most common underlying causes of cardiac arrhythmias, it is essential to monitor and control this problem. Overall, hypercapnia can be corrected rapidly by adjustment of ventilatory rate and tidal volume, use of positive end-expiratory pressure as needed, and reduction of intra-abdominal pressure to 10 mm Hg. The surgeon can also desufflate the abdomen for 5 to 10 minutes to allow the anesthesiologist to “catch up” and correct the hypercarbia; pneumoperitoneum can then be reinitiated at a lower pressure.

In rare cases, if the hypercarbia cannot be controlled by these maneuvers, helium should be substituted for CO₂ as the insufflant. For patients with preoperatively known severe pulmonary compromise, it is prudent to have a tank of helium and the proper helium yoke available in the operating room so the insufflant can be easily switched. Alternatively, argon gas can be used in the acute situation because it is readily available in many operating rooms owing to the argon beam coagulator (Badger et al, 2008).

In the event of cardiac arrest, the surgeon should immediately desufflate the abdomen and provide cardiac massage (compressions) while the anesthesiologist administers 100% oxygen and appropriate drug therapy. If a CO₂ embolus is suspected, additional maneuvers, such as immediately turning the patient to a left lateral decubitus, head-down position and possibly attempting to aspirate the embolus, may be performed.

Changes in Blood Pressure. Hypertension may be caused by inadequate general anesthesia, elevated intra-abdominal pressures, or hypercarbia. Hypotension may be the result of hypoxia, pneumothorax, pneumomediastinum, gas embolus, or hemorrhage (Abdel-Meguid and Gomella, 1996).

In the event of a marked change in blood pressure, one of the aforementioned conditions must be ruled out. The initial response of the surgeon, provided that there is neither active bleeding nor

evidence of retroperitoneal hemorrhage, should be to desufflate the abdomen. In addition, therapy specific to an underlying cause should be enacted.

Aspiration of Gastric Contents. Aspiration of gastric contents may occur more frequently in patients with a hiatal hernia, significant obesity, diabetes with a history of gastroparesis, or any form of gastric outlet obstruction (Hanley, 1992). The combination of elevated intra-abdominal pressures from the pneumoperitoneum, morbid obesity, and use of the Trendelenburg position increases the likelihood of this complication (Abdel-Meguid and Gomella, 1996).

To prevent this problem in high-risk patients, oral or intravenous administration of 10 mg of metoclopramide is recommended. This medication may decrease the incidence of aspiration by increasing the tone of the lower esophageal sphincter. In addition, in patients with known gastroesophageal reflux, H₂ blockers reduce gastric acidity and attendant morbidity if aspiration of gastric contents should occur (Hanley, 1992; Abdel-Meguid and Gomella, 1996). Also, in patients with known gastroesophageal reflux or other predisposing factors for gastric aspiration, a cuffed endotracheal tube should always be placed. Lastly, among these high-risk patients, administration of atropine should be avoided because it decreases the tone of the lower esophageal sphincter (Duffey, 1979).

Hypothermia. The patient's core temperature may drop during prolonged laparoscopic procedures, especially if there is leakage of insufflant around the port sites. The CO₂ that is used is typically neither warm nor humidified. The resulting decrease in temperature may be 0.3° C for each 50 L of CO₂ insufflated (Ott, 1991b). The ambient operating room temperature may exacerbate this effect.

The clinical effects of hypothermia are well described. Core body temperatures around 35° C may result in (1) increased bleeding tendency caused by impaired platelet function, reduced activity of coagulation factors, and enhanced fibrinolysis; (2) increased adrenergic response with vasoconstriction and increased arterial blood pressure; (3) prolonged recovery time as a result of increased blood gas solubility; (4) twofold to threefold increase in the incidence of early postoperative myocardial ischemia in high-risk patients; and (5) impaired wound healing and increased susceptibility to wound infections (Rosenberg and Frank, 1999).

In general there are no specific signs that can be appreciated intraoperatively except for cardiac arrhythmias. In particular, atrial fibrillation may occur in extreme cases of hypothermia (body core temperature of approximately 30° C). In almost all cases, hypothermia can be avoided. Adjuncts to support the patient's body temperature include intravenous fluid warming, active warming by forced-air systems, circulating warm-water mattresses, and radiant heaters (Rosenberg and Frank, 1999). In addition, warming and humidifying CO₂ to physiologic levels, especially when a prolonged laparoscopic procedure is anticipated, is helpful (Ott, 1991a). However, warming the insufflant alone should be avoided, because this causes a drying of the intraperitoneal tissues and has been associated with increased postoperative patient discomfort (Slim et al, 1999).

break in insulation results in an area of very high power density that then discharges to the nearest soft tissue.

Intraoperatively, thermal injuries of the bowel may manifest as whitish spots on the serosal lining. In severe cases, the muscularis mucosae or the intestinal lumen may be seen. However, in many patients, thermal injury to the bowel is not recognized at the time of the procedure. **Postoperatively, the patient with unrecognized bowel trauma may not develop fever, nausea, or signs of peritonitis for many days, as the full extent of bowel necrosis may take up to 18 days to fully develop (Abdel-Meguid and Gomella, 1996).** Therefore, the problem may not become evident until the patient has actually been discharged from hospital.

Accordingly, bowel injury must be ruled out for any patient who develops a fever beyond postoperative day 1 or who complains of increasing abdominal discomfort. Although many patients may have the typical signs of fever, abdominal pain, ileus, and nausea and vomiting, this is not always the case. Instead many patients may have low-grade temperature, leukopenia, and persistent and relatively extreme pain at the trocar site closest to the bowel injury (Bishoff et al, 1999). Alternatively, laboratory values may be remarkable for leukocytosis with an associated left shift (i.e., increased percentage of neutrophils). In some patients, this occurs in the face of a normal or even low leukocyte count, making the left shift a more reliable sign than the absolute white cell count. Abdominal radiographs are notoriously inaccurate because the CO₂ from the laparoscopy may remain as free air for up to 9 days after the procedure; however, an ileus pattern is usually present. A more sensitive test is an abdominal CT scan with oral contrast accompanied by delayed films.

Minor postoperative thermal injuries of the bowel discovered late in the postoperative period (i.e., more than 5 to 7 days postoperatively) may be managed conservatively, aided by administration of antibiotics and an elemental diet. Indeed, a closed fistula may develop that will heal with this approach. However, if the patient does not respond rapidly or develops worsening peritonitis, open surgical exploration is mandatory. Thermal injury caused by monopolar cautery often results in tissue damage that extends beyond the visible area of necrosis. With this in mind, the surgeon should perform a bowel resection with a safety margin of 6 cm on either side before completing an end-to-end anastomosis (Abdel-Meguid and Gomella, 1996).

Thermal injury caused by bipolar electrosurgery is more confined to the visible area of damage. These injuries occur only as a result of direct firing of the instrument on the bowel. If the injury is small, it can be managed by simple excision of the defect and closure of the bowel wall. Bipolar injuries that involve more than half the circumference of the bowel should be treated by excision of the affected segment of the bowel followed by end-to-end anastomosis (Abdel-Meguid and Gomella, 1996).

The goal of every laparoscopic surgery is to never experience a thermal complication. To this end there are several actions the surgeon can take to lessen the risks. First, electrosurgical instruments must be carefully inspected before use for any "breaks" in the insulation; if these are found, the instrument must be sent for recoating. Second, electrosurgical instruments should never be left untended within the abdomen; when not in use they must be removed from the abdomen. Third, *only* the primary surgeon should control electrode activation. Fourth, isolation of the area to be cauterized from the surrounding tissues (vessels, nerves, ureter), as well as use of bipolar electrocautery, reduces the risk of thermal spread and injury to other tissues. Fifth, the electrosurgical device should never be activated unless the entire extent of the metal portion of the instrument is in view. This includes not only the active tip of the instrument, but also any exposed, uncoated metal joints that may lie just behind the tip of the instrument. In this manner both inadvertent direct injury to adjacent tissue and direct coupling to another instrument can be avoided. Sixth, problems of capacitive coupling can be precluded by not creating a situation in which a mixture of conducting and nonconducting elements is used by the surgeon (e.g., metal trocars combined with plastic retainers). In addition, use of modern generators and small-diameter

electrodes can significantly decrease the risk of capacitive coupling (Munro, 1997), as can the use of blended or pure cutting current. The high voltages needed for pure coagulation current pose the greatest threat for electrosurgical injury, especially through the mechanism of capacitive coupling and insulation failure. Lastly, an active electrode monitoring system (Encision, Boulder, CO) is extremely helpful. With this system, any sudden break in the insulation of the electrosurgical instrument (e.g., with scissors or hook electrode) results in immediate shutdown of the electrosurgical current, thereby precluding an electrosurgical injury.

Bowel Injury: Mechanical. Inadvertent mechanical damage can be caused by a wide variety of sharp and blunt instruments (e.g., laparoscopic graspers, scissors, retractors). This type of injury is more visible to the surgeon and is usually discovered intraoperatively or at the end of the procedure. Direct visual identification during the procedure allows the surgeon to repair the injury laparoscopically, even though the patient has not had a formal bowel preparation. Given its localized nature, bowel resection is rarely necessary. The abdomen should be irrigated copiously at the end of the procedure with 4 to 5 L of an antibiotic-containing solution.

If mechanical bowel injury is missed during the procedure, then postoperative symptoms typically develop much earlier than with an electrosurgical injury. Fever, nausea, ileus, and peritonitis develop in the very early postoperative period, and the diagnosis is confirmed by an abdominal CT scan with oral contrast. This type of injury should be managed with immediate return to the operating room to correct the problem by local excision or resection of bowel with subsequent end-to-end anastomosis and copious irrigation of the abdomen.

Delicate handling of tissue with laparoscopic instruments by the main surgeon and the assistants is essential to avoiding this complication. Atraumatic graspers should always be used when handling bowel. Likewise, it is important that all instruments be introduced under strict visual guidance into the peritoneal cavity. Instruments should never be left unattended and should be withdrawn from the abdominal cavity when not in use. Attentiveness, economy of motion, and deftness of touch are essential characteristics of both the successful open and laparoscopic surgeon.

Vascular Injury. Fortunately, direct major vascular injury during laparoscopic dissection is a rare event. The use of only blunt trocars, the small nature of the instrumentation, the limitations on surgical speed, and the magnification of the surgical field by the laparoscope all combine to decrease this potential problem.

During right renal dissection, in particular, the chance of a vena cava, renal vein, or gonadal vein injury is heightened. When this occurs the surgeon can undertake several steps to resolve the bleeding. First, the pneumoperitoneum pressure can be raised to 25 mm Hg, thereby slowing or stopping any venous bleeding. With the use of the irrigator-aspirator, the blood can be cleared and the bleeding site identified. Next, through one of the 12-mm ports, a gauze sponge or pledget can be introduced into the abdomen and handled with a grasping forceps, thereby allowing the surgeon to identify and tamponade the area of bleeding. If the injury is small, then it may respond simply to direct pressure. Alternatively, surgical pharmaceuticals such as fibrin glue or gelatin matrix thrombin sealant (e.g., Floseal [Baxter, Deerfield, IL]) may be applied. If the injury is larger, then the surgeon must decide whether to convert to an open or hand-assist procedure or to attempt to secure and repair the injury laparoscopically. Depending on the severity of injury, a vascular surgery consultation may be appropriate. If a laparoscopic repair is attempted, intracorporeal suturing and possibly the use of a laparoscopic Satinsky clamp may be required. Throughout this period, it is essential for the anesthesiologist to administer sufficient fluids or blood replacement to preclude a hypovolemic state because the hypovolemic patient has a higher risk of possible air embolism at these higher intra-abdominal pressures (O'Sullivan et al, 1997).

If the surgeon is able to gain temporary control of the vessel with a grasper, then it is often helpful to place an extra 5-mm port that can be used by the assistant for suction and irrigation or to optimize the plan of approach to the injury, thereby facilitating laparoscopic

suturing. Either way, the additional port allows the surgeon to repair the bleeding site using two hands and with excellent visualization of the surgical field.

Alternatively, the surgeon can convert from standard laparoscopy to a hand-assisted approach. The hand, in this case, is valuable because it can rapidly tamponade the bleeding site. In this regard it is recommended, if at all possible, to pinch the sidewalls of the vein (e.g., inferior vena cava) closed rather than just putting direct pressure on the top of the injury; the latter approach has a tendency to result in a gradual enlargement of the hole in the vein. Also, if the hole is pinched closed, a Satinsky clamp can be more easily passed beneath the surgeon's fingers to provide reliable control of the injury in preparation for a sutured repair.

Minor arterial injuries usually respond to tamponade. Larger aortic or renal artery injuries are much more difficult to resolve laparoscopically. Although the latter, if it occurs during a planned nephrectomy, can be handled by expeditiously taking the renal artery with a vascular stapler, the former may lead to immediate conversion and open repair. As mentioned earlier, addition of an additional 5-mm port can be very useful to help establish a clear field and provide the surgeon with two hands to control the injury. If conversion to an open procedure is necessary, the area of injury should be tamponaded with laparoscopic forceps and the surgeon can proceed to rapidly make a midline or subcostal incision by swinging one of the ports up to the underside of the abdominal wall and cutting down on the shaft of the port. The tamponading laparoscopic forceps are important to directing the surgeon immediately to the site of injury, which can then be properly repaired. Again, a vascular surgeon should be called into the room as necessary.

As mentioned previously in this chapter, because most bleeding episodes are unexpected, it is wise to have in the room a hemorrhage tray equipped with all instruments necessary to control bleeding and for potential open conversion (see Box 10-3).

Nerve Injury. Nerve injury is invariably a result of patient positioning in combination with the duration of the procedure. The exact incidence of this problem is not known. A survey of neuromuscular injuries associated with laparoscopic urologic surgery completed by 18 urologists from 15 institutions in the United States, published in 2000, found that of a total of 1651 procedures there were 46 neuromuscular injuries in 45 patients (2.8%). This included abdominal wall neuralgia (14), extremity sensory deficit (12), extremity motor deficit (8), clinical rhabdomyolysis (6), shoulder contusion (4), and back spasm (2) (Wolf et al, 2000).

If the patient is inadequately positioned and/or padded, nerve damage may result from abnormal nerve stretching or compression. Among position-related nerve injuries, the brachial plexus appears to be most at risk. Injury may be inflicted in several ways: (1) abduction of the arm beyond 90 degrees, (2) extreme outward rotation of the head of the humerus, and (3) compression damage when shoulder braces are used in the Trendelenburg position (Phong and Koh, 2007), which pushes the clavicle into the retroclavicular space. In particular, this has been reported as a problem with robotic radical prostatectomy when a steep Trendelenburg position is required and strapping the patient might be necessary to avoid slippage. Other nerves that can be affected by positioning include the femoral nerve, because of extreme lateral rotation and abduction of the hip joint, specifically in the lithotomy position, and the sciatic nerve, because of stretching along the superior leg when the patient is in the lateral decubitus position (Hershlag et al, 1990; Abdel-Meguid and Gomella, 1996; Liss et al, 2013). In addition, nerves may be injured during the surgery itself because of either direct mechanical injury or monopolar electrosurgical current.

Nerve palsy caused by positioning is recognized only postoperatively, often on the first postoperative day when the patient tries to ambulate. From both a medical and a legal standpoint, a neurology consultation should be obtained as soon as the patient calls the surgeon's attention to a possible nerve injury. Neurologic examination with possible nerve conduction studies to document acute damage is important. Physical therapy may facilitate recovery. However, recovery in these cases, if it does not occur within the first few postoperative days, is often slow, requiring months.

Prevention is paramount. Table-mounted accessories for all major commercial operating room tables now exist that aid in safely and effectively positioning patients in the lateral decubitus position and in the prone position. If the arms are to be at the patient's sides, they should be pronated to protect the brachial plexus. If the patient is to be in a lateral decubitus position, all bony prominences should be padded with additional gel pads (i.e., hip, knee, and ankle on the downside leg), and a pillow is always placed between the legs. Padding should also be placed beneath Velcro straps and tape, which may be used on the upside hip and shoulder. If the patient is in the lithotomy position with steep Trendelenburg, as is often required during laparoscopic or robotic radical prostatectomy, shoulder braces should not be used owing to risk of brachial plexus injury. Instead, use of well-padded wide straps directly across the upper chest and use of the surgical beanbag (Carey and Leveillee 2007) are excellent ways to secure the patient. Extreme abduction of the hip is also to be avoided; meticulous care to position the patient with attention to hip flexion should be taken when the patient is placed in lithotomy for a prolonged period. Padding must be checked each time the table position is changed, and the patient should be rechecked if he or she is suspected of sliding on the table.

Injury to the Urinary Tract, Spleen, or Pancreas. Similar to open surgery, during laparoscopic or robotic surgical procedures the urinary tract, spleen, or pancreas may be injured.

See the Expert Consult website for a discussion of the incidence, presentation, management and prevention. 

Complications Related to Exiting the Abdomen

Bowel Entrapment. During removal of laparoscopic ports and desufflation of the pneumoperitoneum, omentum or bowel may be entrapped at one of the port sites. If missed during the process of cannula removal, then in the early postoperative period, usually on the second or third postoperative day, the patient may develop an ileus and point tenderness at the port site incision.

The treatment is operative. The pneumoperitoneum is reestablished through one of the unaffected port sites, and three ports are replaced: one for the camera and two for grasping forceps. The entrapped bowel is visualized, and an atraumatic bowel clamp is placed on the bowel on either side of the area of herniation. Once this is done, the skin sutures of the affected port site are carefully cut and the wound is opened. The surgeon uses a fingertip to manually reduce the bowel into the abdominal cavity. The bowel can then be carefully inspected; if it appears viable, which is usually the case, it can be left in place and the port site closed. Rarely are formal bowel resection and reanastomosis required.

This particular problem is the result of a technical error. Indeed, most laparoscopic ports have a hole drilled into the side of the port within a few millimeters of the end of the port's shaft. This hole equalizes the pressure in the port and the abdomen as the port is pulled out of the abdomen, thereby precluding any bowel being withdrawn with the port. Furthermore, if each port site is endoscopically inspected at the time of cannula removal, bowel or omentum that may have entered the port site can be readily identified and positioned back into the abdominal cavity. When the last endoscope-bearing port is removed, the assistant should pull up on the closure sutures or on a fascial clamp, and the surgeon should back the cannula out of the wound and up onto the shaft of the endoscope so that the endoscope is the last thing to leave the abdomen.

Bleeding at the Sheath Site. Bleeding at the sheath site was previously discussed under Complications Related to Placement of Secondary Trocars. However, there are times when this problem does not become apparent until the end of the procedure owing to tamponade from the trocar itself. Again, it is essential to inspect each trocar site at 5 mm Hg to rule out this problem.

Early Postoperative Complications

Pain. Pain may be localized or diffuse. Early in the postoperative course, port site discomfort is to be expected. However, if

Injury to the Urinary Tract

Bladder Injury. Electrocautery and blunt, sharp, and laser dissection have been identified as intraoperative causes of bladder injury (Ostrzenski and Ostrzenska, 1998). Concomitant bladder or pelvic anomalies or pathologic conditions (prior pelvic or bladder surgery, endometriosis, malignant infiltration, bladder diverticula, amyloidosis, or previous radiation) are predisposing factors that increase the chances of this bladder injury (Ostrzenski and Ostrzenska, 1998).

When a bladder injury has occurred, the intraoperative signs may be subtle. One of the first signs is the presence of blood or gas in the Foley catheter bag. Also, the surgeon may notice clear fluid welling up in the pelvis, although this sign is often obscured if irrigation has been used during the procedure.

Postoperatively, if the bladder injury was missed, the patient may develop oliguria and urinary ascites; this may be accompanied by hyponatremia and, rarely, hyperkalemia with mild elevation of the serum creatinine concentration caused by the peritoneal absorption of urine. Patients who have been discharged from the hospital because of the minor nature of their laparoscopic procedure may contact their physician complaining of lower abdominal discomfort, abdominal swelling, fever, and, in the case of a gynecologic procedure, vaginal discharge.

The intraoperative suspicion of a bladder injury may first arise as a result of the recognition of an air-expanded urine collection bag; this presumptive diagnosis can be confirmed by the injection of saline mixed with indigo carmine through the Foley catheter. Postoperatively, the diagnosis can be made by conventional cystogram or CT cystogram.

The intraoperative diagnosis of a bladder injury can be followed by laparoscopic repair—either suturing with absorbable suture or, if the injury is quite small, using preformed suture loops to encircle and secure the cystotomy (Poffenberger, 1996; Ostrzenski and Ostrzenska, 1998). More extensive defects may require open repair.

When bladder injury is diagnosed postoperatively, the key factor is whether the drainage is extraperitoneal or intraperitoneal, which is largely dependent on the preceding laparoscopic access. Extraperitoneal extravasation without any complicating additional problems may be treated by simple placement of a transurethral indwelling Foley catheter. Intraperitoneal drainage is an indication for subsequent laparoscopic or open repair.

Prevention of bladder injury begins with preoperative placement of a Foley catheter. Avoidance of excessive coagulation near the bladder and dissection with exact knowledge of bladder anatomy (urachus, medial umbilical, and vesicocervical ligaments) are also key.

Ureteral Injury. Ureteral injury is usually a result of thermal damage caused by dissection using monopolar electrocautery in the immediate vicinity of the ureter. Its incidence in laparoscopic hysterectomy is 1%; it may also occur during laparoscopic endometriosis ablation and tubal ligation and has been reported during pelvic lymphadenectomy and laparoscopic and robotic radical prostatectomy (Baumann et al, 1988; Grainger et al, 1990; Poffenberger, 1996; Liu et al, 1997; Ostrzenski and Ostrzenska, 1998; Guillon-neau et al, 2002; Yuh et al, 2014).

Typically, ureteral injuries remain unnoticed throughout the laparoscopic procedure. As opposed to a bladder injury, macroscopic hematuria or pneumaturia is distinctly unusual with this injury. The astute laparoscopist might make the diagnosis intraoperatively when urine is seen to be welling up in the wound. However, if irrigation has been used during the procedure this sign is invariably obscured. Within 2 to 3 days after surgery, patients may have abdominal and/or flank pain, fever, signs of peritonitis, and leukocytosis (Grainger et al, 1990; Liu and McFadden, 2000).

The diagnosis of ureteral injury is most often made during the postoperative period when a contrast enhanced abdominal or pelvic CT scan with delayed images is ordered because of the patient's complaint of flank pain, abdominal swelling, hematuria, urinary leakage from the wound, and/or the physical signs of urinary ascites. Depending on the function of the contralateral kidney and the amount of urine leakage, serum chemistries may reveal hyponatremia and, rarely, hyperkalemia with a mild elevation in the serum creatinine concentration.

If identified intraoperatively, the injury can be repaired laparoscopically, but conversion to an open procedure may be required. If the problem is detected in the postoperative period, the first step is to place an indwelling ureteral stent and a bladder catheter. If a stent cannot be placed, then a percutaneous nephrostomy should be placed and an antegrade attempt at stent placement can be made. Depending on the severity of injury, either early laparoscopic or open surgical intervention may be indicated versus a conservative approach.

Prevention of this injury again harkens back to the importance of the surgeon's knowledge of laparoscopic anatomy and the course of the ureter with regard to its topographic relation to other anatomic structures (medial umbilical ligament, round ligament or vas deferens, and common iliac artery). During dissection, monopolar electrosurgical coagulation current should be used with great discretion around the ureter. Ideally, fine-tipped electrosurgical instruments should be used and the duration of discharge should be brief (i.e., multiple short bursts of current rather than a continuous multisecond discharge).

Pancreatic Injury. Injury to the pancreas during left-sided laparoscopic adrenalectomy or radical nephrectomy is most commonly associated with mechanical retraction. The tail of the pancreas overlies the adrenal and may be injured during dissection of the medial aspect of the adrenal and division of the splenorenal ligament. The incidence of this complication is 2.1% for radical left nephrectomy and 8.6% for left adrenalectomy (Varkarakis et al, 2004). Of note, the diagnosis is rarely made intraoperatively, with 75% of pancreatic injuries diagnosed postoperatively.

The typical presentation is postoperatively with abdominal discomfort, elevated serum lipase and amylase levels, and leukocytosis. CT reveals a fluid collection that can often be drained percutaneously. A nasogastric tube is placed and oral intake is stopped. When drainage drops below 50 mL/24 hr, the drain can be removed, followed by removal of the nasogastric tube and initiation of a low fat diet.

Prevention of this complication requires the surgeon to widely dissect the line of Toldt and the splenophrenic attachments. The latter are freed to the level of the diaphragm. The colon is broadly reflected from the Gerota fascia, and the splenocolic and splenorenal ligaments are divided. With these maneuvers the spleen and colon rotate medially, carrying with them the tail of the pancreas, well away from the medial surface of the adrenal gland.

Splenic Injury. The advent of laparoscopic surgery has been associated with a significant decrease in incidental splenectomy during left nephrectomy, with a fall from 4.3% to only 1.5% (Cooper et al, 1996; Breda et al, 2009). These injuries are invariably discovered intraoperatively and can effectively be treated with argon beam coagulation or with one of the newer hemostatic agents such as fibrin glue or thrombin-impregnated granules. **Avoidance of this complication is best achieved by wide mobilization of the spleen during left nephrectomy.** To this end the splenophrenic attachments, as well as the splenocolic and splenorenal ligaments, need to be divided. Retraction in the area of the spleen should never be on the spleen itself but beneath the area of the splenocolic ligament such that the retractor is placed on these thicker tissues (Cooper et al, 1996; Simon et al, 2004).

postoperative pain is limited to a port site, it may also be secondary to herniation (immediate or late), bowel injury, or infection (late). Localized pain combined with a subcutaneous bulge may indicate a rectus sheath hematoma, bleeding and hematoma formation at a port site, or a port site hernia. Pain at a port site without swelling may be due to a particularly broad fascial suture or palpation of the knot of a port site fascial suture in a thin patient. Ultimately, if port site pain appears to be increasing on subsequent postoperative days, herniation should be suspected.

Immediate, severe, diffuse abdominal pain may be related to the release of noxious material during the procedure (e.g., cyst fluid in patients with autosomal-dominant polycystic kidney disease) or to a bowel injury. Immediate postoperative scapular discomfort may be a result of the CO₂ pneumoperitoneum itself causing some irritation of the diaphragm. Rarely, this discomfort may be sufficiently severe to mimic the symptoms of a pulmonary embolus. Of note is that this pain is invariably along the area of the right posterior shoulder region. Delayed diffuse abdominal discomfort and development of peritoneal signs or simply ongoing abdominal discomfort accompanied by low-grade fever may be results of an unsuspected bowel injury.

Incisional Hernia. In adults, the occurrence of an incisional hernia is usually confined to port sites larger than 10 mm. However, in the pediatric population, this complication can occur even with 5-mm ports. The patient usually reports localized discomfort accompanied by nausea and signs of ileus. Rarely, diffuse abdominal pain and/or signs of a complete bowel obstruction may be present. Examination reveals tenderness and, at times, swelling overlying the affected port site. A plain film of the abdomen may show an ileus pattern; however, the definitive study is abdominal CT, which can actually reveal the bowel protruding above the fascial level.

Laparoscopic repair with dissection of the hernia and subsequent intra-abdominal closure can be accomplished. The method for performing this procedure has already been described. In complicated cases in which a strangulated hernia is suspected or confirmed laparoscopically, general surgical consultation should be sought.

As discussed previously, **the risk of incisional hernia can be greatly reduced by using nonbladed as opposed to bladed trocars.** When bladed trocars are used, hernias can be avoided by performing a meticulous fascial suture closure of all trocar entry sites 10 mm or larger in all adults. In children, it is advisable to perform fascial closure of any “bladed” port site 5 mm or larger. The fascial layer is usually closed with an absorbable suture as previously described. **For patients in whom only nonbladed trocars have been used, fascial closure is indicated only of midline ports 10 mm or larger (Kang et al, 2012) or any port site that has been unduly stretched.** Indeed, some authors recommend no closure even of midline nonbladed trocar sites (Siqueira et al, 2004). Although there have been a few reports of a hernia developing after use of a nonbladed trocar (Lowry et al, 2003; Kouba et al, 2007; Zemet et al, 2012), this is distinctly rare. Indeed, the incidence of postoperative hernia formation fell from 1.8% with bladed trocars to only 0.19% for nonbladed trocars (Boike et al, 1995; Hashizume and Sugimachi, 1997; Thomas et al, 2003). Of note, with midline hand-assist approaches, a higher incidence of hernia formation has been identified than would otherwise be expected: 4.0% to 7.3% (Troxel and Das, 2005). Therefore some authors have recommended closure of this midline incision with interrupted nonabsorbable suture rather than a running closure (Troxel and Das, 2005).

In addition, transverse midline fascial incision has been shown to be superior to vertical midline fascial incision for reducing hernia risk (Brown and Goodfellow 2005; Halm et al, 2009). Specifically, for robotic radical prostatectomy the change from vertical to horizontal incisions for the camera port and subsequent prostate removal port site has resulted in a reduction in incisional hernias of 5.4% to 0.4% (Liss et al, 2013).

Deep Venous Thrombosis and Pulmonary Embolism. Although it seems reasonable to expect decreased venous return and hence increased stasis with concomitant higher risk of deep venous

thrombosis (DVT) and pulmonary embolism (PE) in patients undergoing laparoscopy, this is remarkably **not** the case. Indeed, there is no evidence that this complication occurs more often during laparoscopic or robotic procedures versus open surgery (Abdel-Meguid and Gomella, 1996; Secin et al, 2008).

Thus far there have been no randomized controlled trials addressing the issue of DVT prophylaxis in patients undergoing laparoscopic and robotic surgery. The American Urological Association has released a Best Practice Policy Statement for the prevention of DVT in patients undergoing urologic surgery. Noting the lack of data available directly pertaining to laparoscopic and robotic surgery, the panel recommended the use of pneumatic compression stockings placed at the time of laparoscopic procedure for all patients. In addition, they acknowledged that certain high-risk groups may require the use of low-dose unfractionated heparin or low-molecular-weight heparin before, during, or after surgery.

Pneumatic compression stockings should be placed preoperatively and continued for 48 to 72 hours postoperatively. In addition, in morbidly obese patients or in individuals at high risk for thrombosis (smoking, past history of DVT), the addition of unfractionated perioperative heparin (5000 units 2 hours preoperatively and then every 12 hours postoperatively) has also been recommended (Clagett et al, 1995; Capan and Miller, 1999; Secin et al, 2008). Of note, with specific respect to upper retroperitoneal (renal, adrenal, ureter) laparoscopic procedures, at least one study (Montgomery and Wolf, 2005) indicated that sequential pneumatic compressive stockings provide equivalent DVT prophylaxis compared with subcutaneous fractionated heparin and that the use of subcutaneous heparin may increase the incidence of hemorrhagic complications. However, it must be stressed that this was a nonrandomized study obtained from a prospective database augmented by retrospective chart review.

Wound Infections. Overall, this is a rare complication with standard laparoscopy. However, with the hand-assist approach a higher incidence of wound infections has been noted. In one report the postoperative wound infection rate at the hand-assist site was 9% (Nelson and Wolf, 2002). Prevention of this complication is similar to open surgery and includes attention to antiseptic preparation and sterile draping of the abdominal wall, irrigation of each port site at the end of the procedure, and meticulous closure of the wound.

Rhabdomyolysis. Rhabdomyolysis is a devastating complication after laparoscopic surgery. The exact incidence of this problem is not known, but one survey of neuromuscular injuries associated with laparoscopic urologic surgery found that of a total of 1651 procedures there were 6 cases (0.4%) of clinical rhabdomyolysis (Wolf et al, 2000). In a more recent study, it was estimated that the occurrence of this problem among patients undergoing retroperitoneal laparoscopic procedures (e.g., renal, ureteral, adrenal) was higher at 1% (Reisiger et al, 2005). Rhabdomyolysis is invariably associated with male patients undergoing longer laparoscopic renal procedures, especially if the kidney rest has been used for the entire case. Although extra padding applied to pressure areas can be useful in avoiding nerve compression and rhabdomyolysis, gel pads and foam egg crate padding have not been conclusively demonstrated to significantly reduce pressure on the patient's flank in the lateral position (Deane et al, 2008). As discussed previously, **male patients with a BMI of 25 or greater undergoing laparoscopic surgery in the lateral position with the kidney rest elevated and the table completely flexed are at highest risk of developing rhabdomyolysis as a result of flank pressure.**

Rhabdomyolysis manifests immediately in the postanesthesia recovery room with the patient complaining of severe pain in the downside hip area. Brown urine may also be noted. The serum creatine kinase value invariably exceeds 5000 units/dL.

Prevention of this problem is essential. This can, to some extent, be done by avoiding use of the kidney rest or using it for only the earliest part of the case (i.e., less than an hour) and avoiding prolonged periods of hypotension during the procedure (Cadeddu et al, 2001; Kuang et al, 2002; Parsons et al, 2004;

Reisiger et al, 2005). Lastly, with increasing skill and experience, few procedures should proceed beyond 5 hours.

Late Postoperative Complications

Complications beyond the 3-week postoperative period are rare. These primarily include lymphatic complications and incisional hernia. The latter is addressed in the prior discussion because it can also appear as an early postoperative complication.

See the Expert Consult website for further details.

KEY POINTS: COMPLICATIONS AND TROUBLESHOOTING IN LAPAROSCOPIC AND ROBOTIC SURGERY

- Early in one's experience with laparoscopic and robotic surgery, it is wise to apply the minimally invasive approach to low-risk surgical candidates of normal body habitus.
- The first sign of gas embolism is an abrupt increase of end-tidal CO₂ accompanied by a sudden decline in oxygen saturation and then a marked decrease in end-tidal CO₂.
- Electrosurgically induced thermal bowel injury may occur through one of four mechanisms: inappropriate direct activation; coupling to another instrument; capacitive coupling; and insulation failure.
- Careful planning of trocar placement is essential to avoid crossing swords, striking handles, rollover, and robotic arm collisions.

TRAINING AND PRACTICING LAPAROSCOPIC AND ROBOTIC SURGERY

See the Expert Consult website for details.

CONCLUSION

Laparoscopic procedures unthinkable in early 1990 are now performed routinely. Furthermore, the use of a robotic surgical platform to perform complex reconstructive procedures is improving the precision and often the outcomes of these operations and, more important, making it possible for a greater number of urologists to perform high-quality laparoscopic procedures. The widespread adoption of laparoscopy and robotic-assisted laparoscopy highlights the importance of having a detailed and robust understanding of the basics of minimally invasive surgery including the physiologic effects of the pneumoperitoneum, obtaining access, and managing complications. As robotics and flexible endoscopically guided technologies advance in the future, we may see adoption of NOTES and our patients may undergo operations that leave no visible scar. The benefit will be both more proficient laparoscopic and robotic surgeons who can handle any procedure and any complication without the massive incisions of years past, and patients treated with a truly minimally invasive technique. Such should be the next step of our surgical path of discovery and evolution. At that point Osler's 20th century admonition, "Diseases that harm require treatments that harm less," will be truly fulfilled. We are as yet still on the bridge to the future.

ACKNOWLEDGMENT

Lymphocele Formation. Lymphocele formation is most commonly associated with pelvic procedures, such as pelvic lymph node dissection during radical prostatectomy (0.4% to 1.3% incidence) (Kavoussi et al, 1993; Liss et al, 2013) or with renal transplantation (0.6% to 18% incidence) (Bailey et al, 2003). The lymphocele may take weeks to develop and may occur despite a transperitoneal approach. Presentation may be by a mass effect, but the astute clinician should realize that it may also occur as a result of local compression causing lower extremity edema, and, in rare cases, venous thrombosis and PE. The lymphocele is diagnosed readily by CT. **Treatment is percutaneous drainage. Sclerosant therapy can be used to treat the lymphocele; however, if unsuccessful or if the lymphocele is not amenable to percutaneous drainage, then a transperitoneal laparoscopic marsupialization procedure is usually successful.** At the time of the procedure, a tag of omentum can be placed into the opening made in the lymphocele to try to prevent closure of the opening and recurrence.

Prevention of lymphocele formation requires meticulous attention to clipping suspected lymphatic structures. Monopolar electrocoagulation does not work well to seal lymphatics. Bipolar or harmonic devices have been shown to effectively seal lymphatic channels; however, the bipolar device created a seal that was 5- to 10-fold stronger than the harmonic device (Box et al, 2009).

Chylous Ascites. After left-sided retroperitoneal surgery (i.e., left radical nephrectomy, donor nephrectomy), the patient may return complaining of a distended abdomen. Although this complaint is

common in the initial few days after a laparoscopic procedure, because of the pneumoperitoneum, irrigation fluid, and/or ileus, it is distinctly rare late in the patient's course. There is no associated fever, pain, or bowel dysfunction, and routine laboratory study findings are within normal limits. Usually the condition is self-limited and resolves without any intervention. If the presentation is not straightforward, then abdominal CT will reveal the underlying problem and allow diagnosis of the presence of ascites. If tapped, the fluid may reveal elevations in the level of lymphocytes, cholesterol, and triglycerides.

Treatment is usually dietary, with a low-fat, medium-chain triglyceride diet. One may also consider giving somatostatin or octreotide (Leibovitch et al, 2002; Negoro et al, 2006). In the rare situation in which the fluid does not resolve with these conservative measures or if the patient is symptomatic, the fluid can be tapped once or twice. If it continues to accumulate, then an open or laparoscopic exploration is undertaken. Once identified, the leaking lymphatic channel is dissected and secured with either suture or clips (Molina et al, 2003).

Prevention of this type of problem is extremely difficult because the lymphatics are not readily visible during the procedure. In particular with laparoscopic procedures, lymphatic leakage might be overlooked as result of tamponade by the pneumoperitoneum. To date, instances of postlaparoscopic chylous ascites have been cited only sparingly in the literature (Leibovitch et al, 2002; Shafizadeh et al, 2002; Molina et al, 2003; Negoro et al, 2006; He et al, 2011).

Surgeons learning how to perform laparoscopic procedures face several hurdles, including an altered 2D view of a 3D space, counterintuitive control of instruments, different ergonomic constraints, and an altered perspective of surgical anatomy (Piechaud and Pansadoro, 2006). Robotic surgical systems such as the da Vinci Robotic System overcome several of these issues by providing binocular, 3D vision and intuitive instrument motion. However, the robotic system does have its own hurdles to overcome, such as complete lack of tactile feedback and a learning curve regarding the syncope of the surgeon's console. In addition, much like life in general, the only thing constant about laparoscopic and robotic surgery is change. It is therefore necessary for minimally invasive surgeons, no matter how experienced, to master new skills and familiarize themselves with new technologies as they develop. With an ever-increasing emphasis on patient safety and operating room efficiency, it is widely accepted that new surgical skills and techniques should be developed and honed outside the operating room and then transferred into the operating room once proficiency has been developed. The tools and systems available for practicing and acquiring laparoscopic and robotic skills are detailed here.

Equipment for Practicing Laparoscopic and Robotic Surgery

A wide variety of practice models exist for both laparoscopic and robotic surgery ranging from inanimate laparoscopic training boxes to live animal and human cadaveric models. There has also been heightened interest in the development of computer-driven VR trainers that can be used to practice standard techniques and whole procedures. As a general premise, nonliving models should be used unless it is absolutely essential to have a live model.

Standard Laparoscopic Training Boxes

The items necessary for a basic laparoscopic training box are a box with an opaque top that is suitable for placement of laparoscopic ports and a vision system consisting of a video monitor, a light source, and a camera or camera-lens combination. Several commercially available training boxes are available that contain all of the necessary components (Fig. 10-32). Alternatively, one can construct a training box from relatively inexpensive materials such as a cardboard box and a web camera with a computer screen or video camera. Tablets, such as the iPad, are also now readily available and can serve as both the camera and monitor for self-constructed trainers (Ruparel et al, 2014). Although the use of trocars gives a hint of reality, it is not mandatory. In general, the instruments and camera should be configured in a triangular fashion such that the camera lies between the right- and left-hand instruments. For optimal ergonomic positioning, the angle formed between the camera and the right- and left-hand instruments should be 25 to 45 degrees. In addition, the angle between the instruments and the horizontal plane should be less than 55 degrees (Frede et al, 1999). Some more formal training boxes will have built-in camera holders such that one person can practice alone without the assistance of a "camera driver." When possible, however, a camera driver can adjust the lens and camera in, out, up, and down to match the motions of the surgeon. This is most helpful during more delicate maneuvers such as suturing in which panning the view from wide to close-up is essential. This gives the assistant the opportunity to practice "driving camera," which is also an essential skill for laparoscopy. Necessary instruments might include laparoscopic graspers, scissors, and dissectors or essentially any instrument necessary to meet the requirements of the training drill. Practice for basic suturing requires a pair of laparoscopic needle drivers and some suture. A 3-0 suture on an SH needle is best for general practice.

Whether simple or complex, inanimate training models can be placed within standard training boxes and act as the basis for general skill acquisition and progression. Training models for basic tasks such as touching areas of the box at different depths and heights within space, passing objects between instruments and

Figure 10-32. A, Example of a standard laparoscopic training box with a monitor, camera-lens combination, and light source. B, LapED EZ Trainer is a portable briefcase-like box that opens to accommodate a laptop computer that is then connected through the USB port to the contained camera, thereby allowing the laparoscopic skill practice platform to be visualized on the laptop screen.

through and around obstacles, and other helpful maneuvers such as cutting and tissue manipulation can be constructed from common materials such as paper, sponges, rubber gloves or tubing, and other commonly found materials. Alternatively, a wide variety of commercially available models exist that are more realistic looking and may mimic actual operative scenarios more closely (Fig. 10-33).

Alternatively, nonliving animal tissue can be placed within the box trainer for skill acquisition exercises. The advantage of using real, but nonliving animal tissue to construct training models is that it creates a more realistic environment providing closer-to-life tissue handling. Generally the tissues used are inexpensive and can be purchased at a butcher shop or market. The disadvantage is that it requires more intense cleanup after practice. Generally the field inside the training box is set up to mimic a specific surgical scenario and develop specific skills. For instance, the stomach and esophagus of a chicken can be divided and then sewn back together laparoscopically to practice the fashioning of a vesicourethral anastomosis or pyeloplasty (Laguna et al, 2006; Ramachandran et al, 2008).

Live Animal Models. The obvious advantage of use of live animal models is the opportunity to train under more realistic conditions, including more accurate anatomic relationships of tissue and the necessity for hemostasis that does not exist with inanimate models. The disadvantages of use of live animal models are that it requires extensive resources such as a veterinary facility, personnel to care for and provide anesthesia for the animals, and, eventually, euthanasia of the animals. Obviously this can be quite costly. For these

reasons, practicing surgical skills on live animals is not appropriate for daily practice. Instead, these opportunities are usually reserved for formal training courses or when the need for a realistic environment warrants the necessary resources. In general, the species of animal used for practice must have a sufficient peritoneal compartment to provide an adequate working space. For fine procedures, animals as small as rabbits can be used. Swine are the most common animals used for laparoscopic and robotic training because they are readily available, they have the appropriate size peritoneal compartment, and their anatomy mimics relatively well that of humans. It must be noted, however, that the amount of bleeding that comes from a pig kidney (e.g., in partial nephrectomy) is not realistic compared with that of a human. In addition, the porcine bladder is almost completely intraperitoneal.

Figure 10-33. Example of a task-specific training model LapED (4-in-1) model. This model can be used to practice four different urology-specific tasks: (A) vesicourethral anastomosis, (B) dismembered pyeloplasty anastomosis, (C) closure of cystotomy, and (D) renorrhaphy. (From Abraham JB, Abdelshehid CS, Lee HJ, et al. LapED 4-in-1 silicone training aid for practicing laparoscopic skills and tasks: a preliminary evaluation. *J Endourol* 2008;22:1351-7.)

Cadaveric Models. One of the first experiences most medical students have in their training is anatomy, and this entails cadaveric dissection. The reason is simple. Short of operating on real patients, there is no better or more realistic way to learn human anatomy. This holds true for surgical practice as well: however, owing to the major resources necessary to have an anatomic gift program and the significantly high cost for a cadaver compared with alternative models, it is often not practical to use cadavers. If, however, facilities and funding are available and there is a need for practicing a procedure in the most realistic environment, there is no substitute for cadaveric models.

Virtual Reality Trainers

VR trainers are computer-based simulators that offer the opportunity to practice laparoscopic and robotic skills through specific tasks, as well as whole procedures. Typically, trainees view the computer-generated operative field or training drill on a computer monitor and perform tasks using laparoscopic manipulators. The instruments are depicted on the viewer and correspond with the trainee's movements. A major advantage of VR trainers is that they can collect information regarding trainee performance and track progress over time in terms of precision, economy of motion, and other parameters of interest. Because the trainers are computer based, it is possible to develop training programs and curricula including didactics, videos, and live practice sessions. The trainee can progress through the curriculum based on performance. VR trainers have been shown to improve the skills of trainees, helping to prepare them for better performance during live surgery (Seymour et al, 2002; Lucas et al, 2008). In addition, a recent systematic review demonstrated that VR training appears to decrease the operating time and improve the operative performance of surgical trainees with limited laparoscopic experience when compared with no training or with box-trainer training (Nagendran et al, 2013). Several commercially produced VR trainers for laparoscopy are available but are quite costly owing to the advanced technology and software development necessary. These include the LapSim (Surgical Science, Minneapolis, MN), the LAP Mentor (Simbionix, Airport City, Israel), the CAE ProMIS (CAE Healthcare USA, Sarasota, FL), and the Reachin Laparoscopic Trainer (Reachin Technologies, Stockholm, Sweden). Several VR trainers for robotic surgery have also been developed. These include the Robotic Surgical Simulator (RoSS) (Simulated Surgical Systems, Williamsville, NY), the MIMIC dV-Trainer (Mimic Technologies, Seattle, WA), the SimSurgery Educational Platform (SEP) Robot (SimSurgery, Boston, MA), and the da Vinci Skills Simulator (Intuitive Surgical), among several others (Fig. 10-34). All of these VR robotic trainers, however, have been shown to have face, content, and construct validity, and all of these simulators except the SEP Robot have shown educational impact (Abboudi et al, 2013). Lastly, a VR simulator has even been designed for single port laparoscopy, the SEP Single Port (SimSurgery).

Formal Training Programs

Surgical competence is defined by technical and nontechnical skills (Hoznek et al, 2006). Traditionally these skills have been passed down from teacher to apprentice in the process of caring for and operating on real patients during residency training. The technical skills were taught during real operative procedures, and the nontechnical skills such as surgical judgment, problem anticipation and avoidance, economy of motion, and so on were gained by experience of the trainee with supervision from a more senior instructor. In this way, traditional residency programs have been more “learning” programs than “teaching” programs. With ever-increasing emphasis being placed on patient safety, operating room efficiency, and cost containment, there has been a great interest in evaluating the efficacy of formal training programs in laparoscopic and robotic surgery. Such programs offer the opportunity to receive formal instruction in a safe, stress-free environment with the intention of honing both technical and nontechnical skills.

With this concept in mind, one method of concentrated instruction and skill acquisition is the “mini-residency” or “mini-fellowship.” In this training model, surgeons spend a period of several days (typically 5 days) receiving concentrated instruction on a given set of surgical skills or procedures including didactic sessions, clinical case observation, and laboratory training using both

inanimate and animate models. Typically, the attendees also gain access to expert proctors during their initial learning curve for the new procedure. Mini-residency training has been shown to be effective in helping postgraduate urologists incorporate new laparoscopic and robotic procedures into their clinical practices. In one study of laparoscopic renal surgery mini-fellowship trainees at the University of California, Irvine, 73% of attendees were performing laparoscopic renal surgery 3 years later (Kolla et al, 2010). This was also found with robotic surgical training: Of 47 urologists who took a 5-day training course for robotic radical prostatectomy, 90% were performing the procedure in their own practice at 3-year follow-up (Gamboa et al, 2009).

KEY POINTS: TRAINING AND PRACTICING LAPAROSCOPIC AND ROBOTIC SURGERY

- Laparoscopic VR trainers have been shown to improve the skills of trainees, helping to prepare them for better performance during live surgery.
- VR robotic trainers have been shown to have face, content, and construct validity.

Tissue Dissection and Cauterization

Intracorporeal Lithotripters

TISSUE DISSECTION AND CAUTERIZATION

Electrosurgery

Electrosurgery is the application of electrical current to tissue to achieve the effects of cutting, coagulation, desiccation, or fulguration. Monopolar and bipolar electrosurgery techniques are used in urology in numerous applications. An understanding of the basic scientific principles as well as the tissue effects is necessary for the surgeon to use the technology in a safe and efficient manner. Although the technology can be of great assistance to the surgeon, improper settings or poor application can result in patient injury (Massarweh et al, 2006).

Electrosurgical technology was first developed in the late 1800s. The technology originated from spark gap transmitters that were used to generate radio waves at that time. The waveform produced was of a steady frequency but varied in amplitude. Using a combination of inductors and capacitors, the waveform could be smoothed out, although this resulted in some power loss. French scientists in the 1890s experimented with the technology and determined that the raw output from the spark gap transmitter could coagulate tissue, and the smoothed-out current could cut tissue. Around the turn of the 20th century, the technology began to be used in clinical surgical cases in Europe (Van Way, 2000; Massarweh et al, 2006).

In the 1920s, Bovie, an electrical engineer at the Massachusetts Institute of Technology, studied the work of his predecessors and developed a cutting loop that delivered electrical energy that could be used for cutting, coagulation, and desiccation. On October 1, 1926, at the Peter Bent Brigham Hospital in Boston, Cushing used the device to remove a highly vascular myeloma from the head of a patient that previously had been deemed inoperable because of the vascularity of the mass (Van Way, 2000; Massarweh et al, 2006).

Monopolar Electrosurgery

Basic Physics. Electrosurgery uses radiofrequency current in the range of 400,000 to 600,000 Hz to pass through tissue and create the desired effects. The generators deliver more than 100 W of power to the tissue at voltages ranging from 100 to 5000 volts. As the current is delivered to the tissue, the tissue is heated, and the effect occurs. **In contrast, with electrocautery, the instrument itself is heated and then applied to the tissue.** Ohm's law, $\text{Current (I)} = \text{voltage (V)} / \text{resistance (R)}$, applies and states that the current is determined by the applied voltage and the tissue's resistance. The higher the resistance of the tissue, the greater the voltage needed to drive the current through the tissue. Current is calculated as the flow of electrons during a specific period of time. Voltage is used to drive the current through the resistance, which in surgery is the tissue. When alternating current is used, resistance is termed *impedance*. As the resistance increases, the amount of voltage to drive the same amount of current also increases. As tissues become cauterized, their impedance increases, and a higher voltage is needed for the current to penetrate the tissue beneath (Van Way, 2000; Van Way and Hinrichs, 2000; Jones et al, 2006; Massarweh et al, 2006).

Cutting and coagulation currents can be applied and use similar frequencies. For coagulation to occur, the current is interrupted approximately 30,000 times per second. This interruption results in short bursts of radiofrequency energy. For cutting current, the radiofrequency current is delivered continuously (Fig. 11-1). With continuous energy delivery, the cells heat up rapidly to the point of boiling and then rupture, which results in the cutting effect. With coagulation, because the energy is interrupted, the cells are allowed to cool as the energy is cycled off, and the cells dry out instead of rupturing (Van Way, 2000; Jones et al, 2006; Massarweh et al, 2006).

Most generators also offer blended cutting, which adds some coagulation properties to the cutting current. This blended cutting is produced when the cutting current is interrupted similar to coagulation current. In contrast to coagulation current, where the generator output is concentrated into two or three cycles, blended cutting delivers more cycles to the tissue. The number of cycles delivered determines the degree of cutting versus coagulation. For example, a Blend 1 setting may allow 50% of the current through, whereas a Blend 3 setting might allow only 10% of the energy through, resulting in a greater coagulation effect (Van Way, 2000; Jones et al, 2006; Massarweh et al, 2006; Vilos and Rajakumar, 2013).

Modern electrosurgical generators are capable of high voltage and high wattage. This capability allows for either type of current to cut or coagulate. However, differences remain, and the coagulation current results in much more widespread tissue damage and charring but deeper hemostasis owing to the higher voltages used compared with a lower voltage cutting current. **Cutting current employs voltages 10 to 20 times less than coagulation but is still greater than 100 volts. Alternatively, coagulation current is delivered in short bursts at much higher voltage but with less current flow at the same amount of power.** The desiccation of the tissue results in increased impedance and lower current flow compared with cutting. Desiccation results in drying of the tissue and coagulation of blood vessels. The tissue is typically pale and dry with an eschar developing next to the electrode (Goddard et al, 1972; Van Way, 2000; Van Way and Hinrichs, 2000; Jones et al, 2006; Massarweh et al, 2006; Vilos and Rajakumar, 2013).

Fulguration results when the electrode is placed about 2 to 5 mm from the tissue. Electrical energy in the form of a spark arcs from the electrode to the tissue. A coagulation current setting on the generator usually is used, producing a darker char on the tissue with a superficial eschar. Fulguration can be effective at achieving hemostasis, but care must be taken to ensure the eschar is not too superficial, allowing for bleeding deeper in the tissue below the coagulum (Van Way, 2000; Jones et al, 2006).

Argon Beam Coagulator. Traditional monopolar devices do not work well in a liquid environment, such as when there is significant blood in the targeted field. The fluid results in dispersion of the current rendering it ineffective. To address this shortcoming, the argon beam coagulator was developed. **It works by adding a column of argon gas that passes over the electrode, and then electrosurgical energy ionizes the argon gas and helps to displace the blood in the surgical field.** Because it is a noble gas, the current from the electrode is effectively transmitted to the underlying tissue. The

Figure 11-1. Instrument settings relating voltage and current. Pure cut uses continuous delivery, whereas coagulation uses interrupted delivery. Blended modes modify the degree of interruption to desired effect.

current follows the beam of gas and allows for diffuse superficial coagulation; this is ideal for obtaining hemostasis over a broad surface, such as during a partial nephrectomy. Typically, the argon beam coagulator is held slightly farther from the tissue at about 5 to 10 mm. It uses a standard generator and grounding pad but is operated at a higher power setting compared with traditional monopolar cautery in coagulation mode to desiccate the target tissues (Massarweh et al, 2006).

Generator Settings. When adjusting the generator settings, it is important to set the generator at a high enough power setting to achieve effective cutting and coagulation. Setting the generator too low results in an inability of the electrode to cut the tissue and poor or limited effect of the coagulation. For coagulation to occur, approximately 30 to 50 W is needed. For cutting, setting the generator at 60 W is a reasonable starting point subsequently adjusting the power as needed. Typically, fatty tissue is less conductive than muscle and may require higher settings of approximately 80 W. This information is intended as a rough guideline only; experience with individual generators varies (Van Way, 2000; Massarweh et al, 2006; Vilos and Rajakumar, 2013).

Although coagulation current may be used to “cut” tissue using lower power settings, it results in greater collateral damage compared with using a cutting setting. Although it may be reasonable to use coagulation when dividing muscle, it is better practice to use pure cut or cut on a blend setting to produce less charring and less ancillary tissue damage (Massarweh et al, 2006).

Safety

The incidence of electrosurgical injuries is estimated to be 2 to 5 per 1000 (Loffer and Pent, 1975; Nduka et al, 1994; Hulka et al, 1997). Understanding the principles of the electrosurgical devices and operating them within their safety parameters can help to decrease the risk of unintentional injuries.

During monopolar electrosurgery, the patient is part of a complete electrical circuit. Current is initially produced in the generator and is conducted over wires to the electrosurgical electrode. The electrode is used to deliver the current to the surgical site where it is focused. The current is distributed through the patient's body to the dispersive electrode (grounding pad), where it leaves the patient's body and travels over wires back to the generator to complete the circuit. This system is designed to concentrate the energy at the tip of the electrode and then disperse it widely while traveling through the patient's body. If the current is allowed to concentrate in other locations, potential morbidity could ensue.

Most electrosurgical injuries occur at the grounding pad site. Historically, the grounding pad was a metal plate that had contact gel applied to it before placing it in contact with the patient. Modern grounding pads are called dispersive electrodes and function in a similar but safer manner. The old-style metal grounding pads that were used with conductive gel could dry out during a case. Rather than have the current travel through a large contact patch, the dried-out pad could result in a very small contact patch that focused the current and resulted in electrical burns on the skin and underlying structures. Modern dispersive electrodes do not dry out and produce a safer, stable contact patch with the patient. Modern generators have a built-in self-test system that monitors the status of the dispersive electrode. If the generator becomes dislodged or loses contact in some way, the system shuts itself down and the ground fault warning is activated (Nduka et al, 1994; Hutchisson et al, 1998; Alkatout et al, 2012).

Injuries can ensue from inadvertent activation of the electrosurgical electrode. Injury can occur if a foot pedal is accidentally depressed and the electrode burns the drape or burns the patient at a site not intended. Handheld electrodes with a finger actuator are less likely to cause such an injury, although it is still possible. Other injuries can occur if electrosurgical energy is applied to unintended structures during surgery; this can occur when blood vessels and nerves are running close together. For example, the parasympathetic nerves that run near the prostate and are responsible for erections may be inadvertently injured when hemostasis is obtained with coagulation. During laparoscopic nephrectomy, the heel of a monopolar hook electrode may be inadvertently brought into contact with the bowel while activated, resulting in a bowel injury. Keeping the instruments in view, being aware of the surrounding structures, using low but effective power settings, and maintaining a general awareness of the instruments may help reduce such injuries.

The tissues of the body vary in their impedance (ability to conduct electrical energy). Structures such as blood vessels have lower impedance and preferentially conduct and concentrate current, whereas fat has high impedance. Tissue impedance is an important consideration when operating on structures such as the bowel, where current could get concentrated in the thin vascular pedicle that supports the structure. Current concentrated in the pedicle could damage the vascular supply to the tissue.

In patients with pacemakers or implantable cardioversion devices, the manufacturer should be consulted before surgery involving monopolar cautery to ensure that interference with the devices does not occur during surgery. The devices may need to be temporarily deactivated during the procedure.

Prosthetic joints can also affect current conduction but are not an absolute contraindication to use of monopolar cautery. Ideally, the direct path of the electrical circuit should be directed away from the prosthetic joint. For example, if the patient has a right hip prosthesis, the dispersion electrode pad should be placed on the contralateral hip (Massarweh et al, 2006).

Insulation failures can occur if there is a breakdown in the insulating material that surrounds the electrosurgical electrode. Usually only the tip of the electrode is left without surrounding insulation, but if defects occur in other locations, the current may arc out in these spots leading to unintended injuries. Such an occurrence is more likely when higher voltage coagulation modes are used. Reused instruments may be more likely to experience such failures because the defects in the insulation may occur during the reprocessing, although disposable devices could also have defects (Massarweh et al, 2006). Several clinical reports of insulation failures during robotic-assisted laparoscopic surgery have been published (Mues et al, 2011; Cormier et al, 2012). A 33% failure rate of the first-generation robotic monopolar scissors tip cover accessory after one clinical use has been described (Engebretsen et al, 2013).

The surgeon is also at risk for electrosurgical burns. Surgical gloves do not provide much insulation from electrical current. Current can penetrate gloves when they become wet, through capacitance conducting, or when mechanical breakdown of the glove occurs (Tucker and Ferguson, 1991).

Capacitive Coupling. Capacitive coupling is the transfer of energy within an electrical network by means of the capacitance between circuit nodes. Capacitive coupling occurs when two conductive elements are spaced apart by an insulator and energy is stored creating an electrostatic field. When the net charge exceeds the insulator's capacity, current is transmitted from the first conductor to the second. This occurrence is rare but can lead to complications during laparoscopic procedures using electrosurgery. When an active electrode that is surrounded by insulation is passed down a metal trocar, capacitive coupling can occur. However, it can also occur with plastic trocars. The injuries typically occur out of the surgeon's field of vision. An active electrode monitoring system and limiting the amount of time that high-voltage settings are used can decrease the risk of capacitive coupling (Tucker and Voyles, 1995; Vilos et al, 2001; Jones et al, 2006; Wang and Advincula, 2007).

General Safety Tips. Using the lowest possible energy setting that achieves the desired surgical effect is the simplest of the basic principles for the safe use of electrosurgical instruments. Rather than starting at a high setting, the surgeon should slowly ramp up the energy setting until the desired effect is reached. With higher settings, the potential for arcing and capacitive coupling increases. The settings should not exceed settings recommended by the manufacturer.

During surgical use, the electrode tip can become coated with eschar, which causes an increase in impedance and can lead to arcing, spark generation, and ignition of the eschar. A scratch pad can be used to clean the eschar, but this can cause grooves to form on the electrode, which can promote further eschar buildup. Alternatively, a sponge can be used to clean the electrode tip. A sponge effectively clears the eschar and does not cause scratches to the electrode (Massarweh et al, 2006).

A common technique during open surgical procedures is for the surgeon to grasp a bleeding vessel with a forceps or hemostat and then have the assistant touch the instrument with the activated electrode of the Bovie; this delivers current through the instrument to the bleeding vessel. During these maneuvers, the surgeon must be careful not to touch the patient with his or her free hand. Doing so would create an alternative circuit that could allow the current to travel to a different part of the patient's body. Keeping a firm grasp on the forceps can also help to reduce the possibility of current traveling in an alternate path (Hutchisson et al, 1998; Jones et al, 2006; Alkatout et al, 2012).

Basic principles that should be observed include keeping the operating field neatly organized and not tangling cords when multiple corded instruments are used. Care should be taken not to wrap

cords around metal instruments because insulation defects could lead to burns. The handheld electrodes should be secured in an insulated holster when not being used rather than resting them on the patient; this reduces the possibility of burns or injury through inadvertent activation (Massarweh et al, 2006).

Types of Electrosurgical Instruments

Monopolar Devices. Electrosurgical instruments can be divided into two categories of delivery devices—monopolar and bipolar. For monopolar devices, the Bovie is the most widely used example and has broad applications in many surgical specialties including urology. The size and shape of the electrode affect its interaction with the tissue. A smaller contact area results in higher current concentration, whereas a larger contact area results in the current being more dispersed. Greater power settings would be needed with the larger electrode to achieve a similar tissue effect. Many systems allow the surgeon to select the tip appropriate to the given procedure, and the tips can be changed if needed during the procedure to fit the application (Massarweh et al, 2006; Vilos and Rajakumar, 2013).

Bipolar Devices. In contrast to monopolar systems in which a circuit is created by delivering the energy via an electrode and then removed from the patient using a dispersive electrode (grounding pad), bipolar delivery does not require a dispersive electrode. Rather, the active and return electrodes are integrated in the delivery hand piece. The tissue contained between the electrodes is the target tissue.

Bipolar "vessel sealing" devices have been developed that use computing technology built into the electrosurgical generators. These closed-looped feedback systems allow for vascular structures up to 7 mm in diameter to be fused and can help obviate the need for sutures, clips, or surgical staples. Several studies have confirmed the effectiveness of such devices demonstrating clinically equivalent burst pressures when compared with surgical staples, sutures, and titanium clips. Compared with the harmonic scalpel, burst pressures were higher for vessels 4 to 7 mm in diameter (Kennedy et al, 1998; Harold et al, 2003; Landman et al, 2003; Takada et al, 2005). The LigaSure vessel sealing system (Covidien, Dublin, Ireland) has been used successfully for radical prostatectomy and cystectomy with a benefit in operating time and blood loss demonstrated compared with conventional vessel ligation. However, long-term damage to neurovascular structures was not addressed in these studies (Sengupta and Webb, 2001; Daskalopoulos et al, 2004). In a study comparing the use of the LigaSure device with a harmonic scalpel during laparoscopic radical prostatectomy, a benefit in functional outcomes including return to continence and erectile function was demonstrated in favor of the LigaSure device (Pastore et al, 2013).

Ultrasonic Instrumentation (High-Frequency Vibratory Device)

Ultrasonic devices offer an alternative to electrosurgical instruments. These devices have elements that vibrate at ultrasonic frequencies of approximately 55,000 Hz. Mechanical energy and heat are generated, and these cause the denaturation of proteins and the formation of a coagulum that can seal small vessels. Depending on the instrument, vessels 2 to 3 mm in diameter can be sealed, and vessels up to 5 mm in diameter can be sealed with some newer instruments. Newer instruments also produce less heat and charring to the surrounding tissue, limiting thermal injury. The heat generated is usually less than 80° C. The device is best applied to the tissue in a tension-free manner; this allows the instrument to divide the tissue effectively while coagulating at the same time, limiting blood loss. Aerosolized fatty droplets may develop as the tissue is divided, and this can negatively affect visualization through the laparoscope. Examples of such devices are the Ultra Shears (Covidien), Harmonic Scalpel (Ethicon Endo-Surgery, Johnson & Johnson, New Brunswick, NJ), and Thunderbeat (Olympus, Tokyo, Japan). Devices for open and

laparoscopic surgery have been developed. The Harmonic Scalpel has been shown to allow for effective tissue dissection and bleeding control during laparoscopic partial nephrectomy (Harris, 1978; Helal et al, 1997; Tremp et al, 2011).

A study comparing the vessel sealing times and thermal spread of two bipolar vessel sealing systems (LigaSure and PK [Gyrus ACMI, Southborough, MA]) and an ultrasonic device (Harmonic Scalpel) was performed. This study demonstrated that the two bipolar systems had faster vessel-sealing times with higher burst pressures compared with the ultrasonic device. However, the ultrasonic device had less thermal spread and smoke production (Lamberton et al, 2008). The smoke plume produced by ultrasonic devices may also be less toxic compared with electrosurgically generated smoke (Fitzgerald et al, 2012).

Laser Instrumentation: Soft Tissue Applications

A laser is a device that emits light through the process of optical amplification by the stimulated emission of electromagnetic radiation. The word *laser* is derived from an acronym for “light amplification by stimulated emission of electromagnetic radiation.” In the 1980s, lasers first became of interest to researchers and clinicians in urology, and at the present time a wide range of lasers are employed to treat various soft-tissue and stone conditions. Although the holmium:yttrium-aluminum-garnet (Ho:YAG) laser has become the accepted gold standard for the treatment of urinary calculi at this time, various wavelengths of lasers are employed to treat soft-tissue conditions such as stricture disease, benign prostatic hyperplasia (BPH), urothelial cell cancer, and genital skin lesions (Marks and Teichman, 2007; Heinrich et al, 2010; Zarrabi and Gross, 2011).

Lasers are a source of electromagnetic radiation that emit a beam of energy that may include nonoptical wavelengths and visible light. The properties of this light create the therapeutic effects used during surgical procedures. General components exist with all lasers including an energy source, an active medium, and a resonant cavity. Light is generated with the active medium, which can be a solid, liquid, or gas. For the laser action to occur, most of the atoms or molecules within the active medium must be brought simultaneously to a higher energy state by an energy source; this is also referred to as pumping. The energy source energizes the atoms in the active medium and produces a population inversion, which is an excited state in which the atoms or molecules are primed for stimulated emission (Troup, 1963; Siegman, 1986).

Numerous types of energy sources drive lasers. Broadly, either electrical current or a different wavelength of light is used. The pump light can be generated by a flash lamp or a different wavelength laser. The specific energy source used depends on the type of laser; however, all are designed to produce laser light in a collimated beam (Siegman, 1986; Teichmann et al, 2007).

Light exists as electromagnetic waves representing spatial concentrations of energy. Each wave exists as a bundle of energy or as a particle called a photon. Photons are emitted and stimulate surrounding atoms and cause additional photons to be released. These have the same energy and travel in phase with the initial stimulating wave. The result is that the entire light is the same wavelength and travels in the same direction. The highly ordered, in-phase light arrangement is termed *coherence*. A long tube or cylinder is ideal for this process but not practical. A resonant cavity is created using mirrors to reflect light, allowing it to have many passes through the medium. A small portion of the amplified light escapes out of the resonant cavity and forms the beam of laser light (Stein and Kendall, 1984a; Stein, 1986; Welch et al, 1989).

Laser light has specific properties. It is monochromatic and of a single wavelength. The light is coherent with a uniform spatial relationship between all portions of the electromagnetic wave. It has directionality with minimal divergence, which allows it to maintain brightness over long distances. It is the high concentration of the bright laser light when focused on a small spot that gives it the properties to be a useful surgical tool but also a potential hazard (Stein and Kendall, 1984a; Welch et al, 1989).

The wavelength of laser light can vary and may be in the ultraviolet, the visible, or the infrared portions of the optical spectrum. Most lasers emit one or a couple of wavelengths; examples include the argon (488 nm—blue; 514 nm—green), the neodymium:YAG (Nd:YAG; 1064 nm and 1318 nm), and the Ho:YAG (2100 nm) lasers (Stein and Kendall, 1984a; Teichmann et al, 2007).

Pulsed and Continuous Wave Lasers

Depending on how the excitation energy is applied and how the laser cavity is configured, the output beam of laser light is either pulsed wave or continuous wave. The duration and energy of individual pulses can vary and depend on the type of laser. Pulses may be delivered individually, in groups, or continuously over a wide range of frequencies. A laser is considered continuous wave if the output emission is greater than 0.25 second. Clinically, a continuous wave laser delivers output that is continuous and of a constant amplitude; this allows for a stable, easy-to-control instrument. In contrast, a pulsed wave laser delivers bursts of energy, which works well for stone fragmentation but may be more difficult to control during soft-tissue interactions (Teichmann et al, 2007; Zarrabi and Gross, 2011).

The power of the laser is equal to the energy over time ($P = \text{energy/time}$ or $W = J/\text{sec}$), and a high degree of power can be reached with even a small amount of energy if very short pulses are used. Several techniques exist that can compress or shorten the pulse. Examples include Q-switching and mode locking. Q-switching involves interrupting the light beam in a controlled fashion so that the laser action is delayed until maximal population inversion has occurred in the active medium. It generates lower pulse repetition rates, higher pulse energy, and longer pulse duration compared with mode locking, another technique used to shorten the pulse. Mode locking, which can be combined with Q-switching, can create ultrashort pulses by fixing the way photons bounce back and forth in the resonant cavity. It can create very high power pulses because of their ultrashort duration (Stein and Kendall, 1984a; Teichmann et al, 2007; Zarrabi and Gross, 2011).

Delivery Systems

All medical lasers have a delivery system that allows for the laser energy to be directed to the intended target site. Delivery systems may be fixed rigid systems such as articulating arms or flexible systems such as fiberoptic glass fibers. Fiberoptic systems are generally inexpensive and quite versatile; however, fiberoptic materials are unable to transmit all laser wavelengths. For example, the carbon dioxide (CO₂) laser, with a wavelength of 10.6 μm , does not pass through quartz or glass fiber optics, and instead a more rigid system composed of an articulating arm with a series of mirrors is employed. The final tissue interface usually contains a focusing device to optimize the laser energy delivery (Stein and Kendall, 1984a, 1984b; Marks and Teichman, 2007; Teichmann et al, 2007; Zarrabi and Gross, 2011).

Light-Tissue Interaction

Laser light is absorbed by tissue in a wavelength-dependent fashion. However, some of the light, independent of the wavelength, may be reflected by the boundary layer of the tissue. This light is lost for the surgical purpose and may cause heating and collateral damage in the surrounding tissue. The optical properties of the tissue and the surrounding irrigant can affect the degree of reflection. Because this process is not dependent on the wavelength, reflection is often not considered when selecting a wavelength for surgical lasers (Teichmann et al, 2007).

Some scattering of the laser energy may also occur. By scattering, some of the intended laser energy is taken out of the surgical field. The degree of scattering varies with the wavelength of the laser. Typically, lasers with shorter wavelengths have a much greater amount of scatter compared with lasers of longer wavelengths. This

Figure 11-2. Comparison of various laser wavelengths and absorptions in various media. CO₂, carbon dioxide; Er:YAG, erbium:YAG; Hb, hemoglobin; HbO₂, oxyhemoglobin; Ho:YAG, holmium:YAG; KTP, potassium titanyl phosphate; Nd:YAG, neodymium:YAG; SHG, second harmonic generation; Tm:YAG, thulium:YAG.

is an important consideration in selecting an appropriate laser for surgical applications (Teichmann et al, 2007).

The most important light-tissue interaction is absorption. When the laser beam enters into a medium in which it is absorbed, the intensity of the laser energy decreases in an exponential fashion that is consistent with Beer-Lambert law. This law states that a logarithmic dependence exists between the transmission of light through a substance, the product of the absorption coefficient of the substance, and the distance the light travels through the material. Absorbed laser energy is converted to heat and increases the temperature of the target tissue. If enough heat is generated, coagulation and subsequently vaporization can occur. A chromophore is required for absorption to occur. In the body, melanin, hemoglobin, and water are available chromophores with hemoglobin and water being most important for urologic applications (Teichmann et al, 2007; Zarrabi and Gross, 2011) (Fig. 11-2).

Types of Lasers

Neodymium:Yttrium-Aluminum-Garnet. The Nd:YAG laser has a wavelength of 1064 nm and has a tissue depth of penetration of about 1 cm. It has hemostatic and coagulative tissue properties. Historically it has been used in urology for the treatment of BPH with visual laser ablation of the prostate (VLAP) and interstitial laser coagulation of the prostate. During VLAP, a side-firing laser fiber is used to direct the laser beam at 60- to 90-degree angles. The fiber is held off the prostatic tissue, and an area of heat-induced coagulative necrosis is produced as the tissue is targeted. The coagulated tissue is not entirely cleared at the time of surgery, but rather a sloughing process occurs in the weeks after surgery with associated edema. Prolonged postoperative catheterization may be needed in 30% of individuals (Norris et al, 1993; Cowles et al, 1995; Muschter, 2003).

Interstitial laser coagulation of the prostate involves placing laser-diffusing fibers directly into the adenoma of the prostate and can be performed either transurethral or via a perineal approach. Similar to VLAP, the tissue undergoes coagulative necrosis and subsequently atrophies. The procedure can be safely performed in anticoagulated patients, but significant postoperative tissue edema can occur. Prolonged periods of catheterization after surgery—often 7 to 21 days—are required because of the high risk of urinary retention. Published re-treatment rates of up to 20% at 2 years and 50% at 54 months suggest poor long-term durability (Perlmutter and Muschter, 1998; Daehlin and Frugard, 2007). With the advent of newer laser technology and techniques, the use of the Nd:YAG laser for BPH has largely been abandoned.

Potassium Titanyl Phosphate. The potassium titanyl phosphate (KTP) laser, commonly referred to as the “green light” laser, is a frequency-doubled Nd:YAG laser. The Nd:YAG laser beam is passed through a KTP crystal, which results in doubling of the frequency and halves the wavelength to 532 nm resulting in a visibly green laser beam. This wavelength is strongly absorbed by hemoglobin and in well-vascularized tissue has only 1 to 2 mm of tissue penetration compared with 10 mm for the standard Nd:YAG laser. The KTP laser is widely used for photoselective vaporization of the prostate in which the well-vascularized prostate tissue is treated in a noncontact fashion with a side-firing laser fiber. The targeted tissue quickly increases in temperature above the boiling point and is vaporized leaving behind a rim of coagulated tissue that provides a layer of hemostasis. In contrast to VLAP, the limited depth of tissue penetration results in less tissue edema, and prolonged catheterization is usually not required (Barber and Muir, 2004; McAllister and Gilling, 2004; Teichmann et al, 2007; Zarrabi and Gross, 2011).

The early KTP laser systems were low-powered 34-W systems and were used in conjunction with a standard Nd:YAG laser. A hybrid surgical technique evolved in which the surgeon first performed a VLAP with the Nd:YAG laser and then used the KTP laser to perform bladder neck incisions. The goal was to try to reduce the prolonged catheterization and bothersome postoperative lower urinary tract symptoms after standard VLAP (Barber and Muir, 2004). Subsequently, a higher powered 60-W KTP laser was developed. This KTP laser was a pulsed wave system but allowed for rapid delivery of the pulses that simulated the effect of a continuous wave laser. This laser permitted the photoselective vaporization of the prostate procedure to be performed independently of the standard Nd:YAG laser. Further refinement resulted in the development of an 80-W KTP laser, which demonstrated favorable outcomes and complications comparable to traditional transurethral resection of the prostate (TURP) (Kuromatsu et al, 2006; Ruszat et al, 2008).

Lithium Triborate. The 120-W lithium triborate (LBO) laser was developed in an effort to increase the efficiency of the tissue vaporization compared with the 80-W KTP laser, especially for men with large prostates in whom procedures remained time-consuming (Wosnitzer and Rutman, 2009). The LBO remains a 532-nm wavelength laser. The higher power allows the distance between the fiber tip and the target prostate tissue to be increased to 3.0 mm versus 0.5 mm for the KTP laser. The greater distance may help preserve the laser fiber and make it technically easier to use. However, hemostasis with the higher-powered system appears to be less compared with the 80-W system (Heinrich et al, 2010). Most recently, a 180-W LBO laser that works in conjunction with a liquid-cooled fiber

delivery system (GreenLight XPS, AMS, Minnetonka, MN) was developed to increase efficiency further. The European GOLIATH study confirmed efficacy similar to TURP, and a North American multicenter trial demonstrated shorter laser and operating times for the 180-W system compared with 120-W systems (Hueber et al, 2013; Bachmann et al, 2014). However, a steeper learning curve has been reported with the 180-W systems, with up to 120 procedures needed to work through the process and handle the higher power of the system safely and effectively (Misrai et al, 2014).

Diode. Diode lasers with wavelengths of 808 to 980 nm are absorbed well in water and behave similarly to Nd:YAG lasers (Orihuela et al, 1996). However, the laser is much more efficient than the Nd:YAG and requires only a standard wall plug for operation; this allows for a smaller, more portable laser design with fewer cooling requirements. More recently, interest in the diode laser as a tool for the surgical management of BPH increased. The 980-nm diode laser was used when the higher powered LBO lasers were found to be not quite as effective in terms of hemostasis compared with the older 80-W KTP lasers. The diode laser appears to provide better hemostasis compared with the LBO laser but a higher complication rate; postoperative frequency and urgency and epididymitis have been associated with its use (Chiang et al, 2010).

Holmium:YAG. The Ho:YAG laser is a 2140-nm pulsed laser that is used for soft-tissue and lithotripsy applications in urology. The 2140-nm wavelength is strongly absorbed in water, traveling only about 0.5 mm in the fluid medium, making it ideal for the urologic environment. In the prostate, the absorption depth is about 0.4 mm resulting in a high-energy density that leads to the rapid vaporization of tissue. Heat is also generated during this process and allows for coagulation of small blood vessels up to a depth of approximately 2 mm.

It is held that the onset of vaporization occurs in the irrigant that is adjacent to the tip of the laser fiber. With each pulse of the laser, a steam bubble of a few millimeters in diameter is created. The bubble is not visible because it is present for only about 500 μ sec—about the same length of time as the laser pulse duration. During holmium laser enucleation of the prostate (HoLEP), the laser pulses create the steam bubbles, which lead to the separation of the prostatic adenoma from the capsule of the prostate. Tissue vaporization occurs and leads to the white fibrous appearance of the tissue. The heat generated during the process allows for hemostasis to occur in the adjacent tissue. For persistently bleeding vessels, the laser can be “defocused” by increasing the distance between the fiber tip and the target bleeding vessel; this results in only the coagulation effect occurring with limited or no vaporization.

Before the development of the HoLEP technique, the use of the Ho:YAG laser for the treatment of BPH went through a series of steps. Similar to the KTP laser, the Ho:YAG laser was initially combined with the Nd:YAG laser to perform hybrid techniques in which the Nd:YAG was used first to perform VLAP, and then the Ho:YAG was used to make bladder neck incisions that reduced the need for prolonged postoperative catheterization (Gilling and Fraundorfer, 1998). These hybrid techniques subsequently led to holmium laser ablation of the prostate in which the laser energy was used to vaporize the prostatic tissue. This was a relatively easy procedure to learn but did require a high-powered Ho:YAG laser (80 to 100 W) and a side-firing laser fiber. However, the rate of vaporization was slow, and long procedure times were needed to treat men with large prostates adequately. The side-firing fibers would also fail if held too closely to the tissue, likely owing to thermal breakdown (Tan et al, 2003). The development of holmium laser resection of the prostate followed. This technique involved cutting pieces of the prostate off as it was resected, similar to a TURP. The sizes of the pieces could be larger than typical TURP chips but had to be small enough to be able to irrigate them out of the bladder at the completion of the resection. This technique was more challenging than holmium laser ablation of the prostate and remained time-consuming in patients with large prostates (Cresswell et al, 1997).

The next development was HoLEP, in which the median and two lateral lobes are enucleated and pushed into the bladder in a manner mimicking an open prostatectomy. Before the introduction

of an effective tissue morcellator, some surgeons employed a traditional transurethral resection loop to cut up the adenoma in the bladder after the enucleation was completed. However, the tissue morcellator streamlined this process, and although it still carries with it the risk of bladder injury, it would appear to be much safer and less cumbersome than using a transurethral resection loop. HoLEP is performed in an almost bloodless field as a result of the coagulation produced by the Ho:YAG wavelength but also as a result of the extensive blunt dissection from the tip of the endoscope, similar to the use of a surgeon's finger during an open retropubic prostatectomy (Elzayat and Elhilali, 2006). HoLEP has proven to be a highly effective procedure with durable long-term results in men undergoing surgical management of BPH. It is effective for men with a broad range of prostate sizes and can be performed in men on anticoagulation (Elzayat et al, 2005, 2006; Tyson and Lerner, 2009; Krambeck et al, 2010). However, adoption of HoLEP has been slowed by the steep learning curve and the availability of other techniques that are easier to learn (Bae et al, 2010).

Thulium:YAG. The thulium:YAG (Thu:YAG) laser is a continuous wave laser operating at a wavelength of approximately 2000 nm. It differs from the Ho:YAG laser in that the thulium ions are excited by high-power laser diodes as opposed to flashlamp excitation with the Ho:YAG. As a result, there is less heat generation and increased power efficiency by a factor of five with the Thu:YAG laser, and no special electrical installation is needed to operate the laser (Teichmann et al, 2007). The slightly shorter wavelength compared with the Ho:YAG laser results in slightly less depth of tissue penetration. The continuous wave output promotes more of a direct cutting action of the laser versus tissue tearing and splattering with the pulsed output of the Ho:YAG. As the tissue is cut with the Thu:YAG, a seam of coagulated tissue is created and produces hemostasis. The coagulated tissues retain some water for efficient absorption of the laser energy during subsequent tissue passes (Teichmann et al, 2007).

Similar to other lasers, the Thu:YAG has been used in a variety of manners to treat BPH. Early reports described a tangerine technique in which the prostate was cut into slices with the laser (Xia et al, 2005). Hybrid techniques involving both vaporization and resection (vaporesction) were developed and shown to be effective (Bach et al, 2010). Thulium laser enucleation of the prostate followed and was demonstrated to have results similar to HoLEP (Lancono et al, 2012; Zang et al, 2012).

Carbon Dioxide. The CO₂ laser produces a beam of infrared light with a wavelength of 9.4 to 10.6 μ m. It is strongly absorbed by water and used for numerous medical purposes including dermatologic applications. It is a continuous wave laser and highly efficient with a ratio of output power to pump power of 20%. The infrared beam is delivered with a rigid arm containing a series of mirrors (Stein and Kendall, 1984b; Malek, 1992). In urology, it is primarily used to treat skin lesions such as condyloma, but it is also used to treat penile carcinoma when an organ-preserving strategy is employed (Finkelstein, 1984; Bandieramonte et al, 2008; Colechia et al, 2009).

INTRACORPOREAL LITHOTRIPTERS

Table 11-1 summarizes characteristics of commonly used intracorporeal lithotripters.

Electrohydraulic Lithotripsy

Electrohydraulic lithotripsy (EHL) has been implemented in biliary, pancreatic, and renal calculi. Initially employed in 1950 for bladder stones using 9-Fr probes, renal applications through flexible ureteroscopy became possible with technologic advances. First described in 1988, at a time when laser fiber technology was unable to flex in the same way, EHL became an innovative strategy to treat lower pole kidney stones endoscopically. Since then, more contemporary modalities have improved efficiency, while minimizing complication risks.

TABLE 11-1 Characteristics of Commonly Used Intracorporeal Lithotripters

MODALITY	BLADDER	URETER	KIDNEY	FLEXIBLE	CONTACT	MECHANISM OF ACTION	TISSUE EFFECTS	ADVANTAGES	DISADVANTAGES	PROBE SIZES (FR)
EHL	✓	✓	✓	✓	1 mm from stone	Electrical spark produces vapor bubble and subsequent cavitation bubble creates shockwaves that fracture stones	>1 mm distance from mucosa <500 mJ—no injury >1000 mJ—ureteric perforation	Able to reach lower pole Inexpensive	Significant tissue damage at higher energy Durability of probe tip	1.6, 1.9, 3.3, 9
Ultrasonic	✓	✓	✓	✓	Direct contact	Rapidly vibrating probe tip results in fragmentation, while simultaneous aspiration removes debris	Mucosal stripping No muscularis damage	Most efficient single modality In-line suction for simultaneous stone removal	Reduced efficiency in hard stones	2.5, 3, 4.5, 9
Pneumatic	✓	✓	✓		Direct contact	Ballistic tip repeatedly strikes stone similar to jackhammer	Focal areas of hemorrhage and mucosal erosions Least traumatic of all intracorporeal lithotripters	Least traumatic Works well on harder stones Least expensive	Least efficient Significant retropulsion	2.4, 3, 4.8, 6, 10.5
Ho:YAG laser	✓	✓	✓	✓	Direct contact	Photothermal energy transfer rapidly heats and disintegrates stone producing fine fragments	Thermal injury to depth of 0.5-1.0 mm	Flexible enough to reach lower pole Smallest fragments Works on all stone compositions Can be used for nonstone indications	Mucosal injuries with 0.5-1 mm depth of penetration Fiber breakage can damage flexible scope High initial cost	200-μm, 365-μm, 550-μm, 1000-μm
Combination ultrasonic/pneumatic	✓		✓		Direct contact	Simultaneous pneumatic and ultrasonic lithotripsy	Subepithelial denudation, muscularis rupture	More efficient than pneumatic or ultrasonic alone Works on all stone compositions	Only rigid probes available Requires large-diameter working channel	9.9 (Swiss LithoClast Ultra) 11.25 (CyberWand)

EHL, electrohydraulic lithotripsy; Ho:YAG, holmium:YAG.

Physics and Mechanism of Action

Two electrodes are positioned at the tip of the probe, creating a spark when triggered. Immersed in a liquid, the electrical spark creates an immediate transition from fluid to gas, creating a rapidly expanding plasma shockwave radiating from the spark outward 360 degrees. The collapse of this shockwave creates a cavitation bubble, which creates a secondary shockwave and high-pressure microjets (Vorreuther et al, 1995).

By adjusting spark discharge, the electrical and subsequent acoustic fragmentation potential can be optimized. Vorreuther and Engelking (1992b) identified that higher voltage shocks produce linearly increasing peak pressures and steeper shockwave fronts. Lower capacity probes produced shorter currents and shorter sparks with more narrow pulse widths. Because fluid vaporization provides the force required for fragmentation, a small space between the probe and stone is recommended during fragmentation. Typically, 1 mm is required because increasing the probe-to-stone distance leads to exponential decreases in shockwave power.

Probes between 1.9 and 3.3 Fr are available. Thinner probes are considered more versatile because of their application in flexible and semirigid ureteroscopy. Reducing probe diameter does not clearly lessen fragmentation potential; however, durability is decreased (Elashry et al, 1996). Pressure generated by EHL probes is estimated using the formula: Maximum pressure = energy/(pulse duration × fiber cross-sectional diameter).

Tissue Effect

Vorreuther and colleagues (1995) attempted to quantify tissue damage resulting from the use of a 3.3-Fr Wolf EHL probe. Using freshly harvested human ureters, histologic changes were measured after direct contact with the EHL probe. At 100 mJ, only punctate mucosal injuries were noted, whereas increasing to 400 to 600 mJ caused superficial mechanical defects in the muscularis. Increasing the energy to 1000 mJ caused transmural perforations. Microscopically, no thermal injuries were noted, and defects appeared to be due to mechanical disruptions, although limited to the cross-sectional diameter of the probe. When maintaining constant energy levels, altering voltage and/or capacity did not affect the resulting histologic findings. No damage was encountered at a distance of 1 mm between the probe tip and mucosa, even at maximal energy and pulse rates (Vorreuther et al, 1995). In a porcine model, bladder exposure to varying energy and total pulse numbers was performed using a 3-Fr probe. Scanning electron microscopy identified that the depth of mechanical mucosal denudation correlated independently with the energy setting and number of delivered pulses (Wu et al, 1994).

When tested in an intact ureter, the probe tip was centered in the lumen, and no histologic damage was encountered at energy settings less than 500 mJ/pulse. When energy levels reached 1000 mJ, a single pulse could produce a 1-cm longitudinal ureteric perforation. Thought to be secondary to cavitation bubbles, which can reach 1.5 cm in diameter at greater than 1300 mJ, the rapid expansion effectively burst the ureter (Vorreuther et al, 1995). The safe use of this (and any other) lithotripter requires a working knowledge of the physics behind stone fragmentation and the collateral effects on surrounding fluid and tissues (Fig. 11-3).

See the Expert Consult website for further details.

Chemical stone composition has been shown to affect fragmentation efficiency during EHL ureteroscopy. A review of operating room times for 193 patients was compared with the chemical composition of ureteric stones. Uric acid stones required the most time, followed by calcium oxalate monohydrate, and in multivariate analysis, stone size was negatively associated with successful fragmentation (Song et al, 2012). This association may be due to the smooth outer surface and lamination of uric acid stones being more difficult for shockwave-generated fragmentation.

See the Expert Consult website for further details.

Figure 11-3. A, Electrohydraulic lithotripter probe spark producing a concentric shockwave within the ureter. B, Higher energy settings create cavitation bubbles up to 1.5 cm, increasing the risk of ureteric injury and/or perforation.

KEY POINTS: ELECTROHYDRAULIC LITHOTRIPSY

- EHL probes create a spark, which produces a rapidly expanding plasma shockwave and cavitation bubble with high-pressure microjets.
- Increasing the distance from the target reduces its peak pressure exponentially.
- At less than 500 mJ, mucosal injuries are rare; at greater than 1000 mJ, the risk of tissue damage is increased.
- A 1.9-Fr probe can be used with flexible ureteroscopy and allows active deflection for acceptable rates of stone fragmentation in all calyces.
- Chemical stone composition and surface characteristics affect the efficiency of EHL fragmentation.

Pneumatic Lithotripsy

Pneumatic lithotripsy provides a versatile and dependable approach to urolithiasis throughout the genitourinary tract. Early clinical reports confirmed the efficacy of pneumatic lithotripsy, and success rates of 95% (Teh et al, 1998) have been reported. With good fragmentation effect in hard stone compositions and attractive safety ratings, it continues to be popular globally in upper and lower tract stone disease.

Basic Physics

Pneumatic lithotripsy uses ballistic forces to transfer kinetic energy from a handheld probe to the stone surface (Michel et al, 2008). Either compressed gas (medical air or CO₂ cartridges) or electromagnetic oscillations are used to drive a projectile forcefully against the probe tip, thrusting it forward like a piston. Repetitive strikes (LithoClast [Boston Scientific, Marlborough, MA/Electro Medical Systems, Dallas, TX]), 12 Hz; electrokinetic lithotripter, 15 to 30 Hz) from the probe tip act as a jackhammer, fragmenting stones at the point of contact. When applied to compliant surfaces such as soft tissue, the impact energy is absorbed and dispersed, whereas rigid objects are not compliant resulting in fracture. Pneumatic lithotripters are safe for use in close proximity to the mucosa because soft tissue injuries from probe contact are relatively mild (see later). Other advantages of pneumatic lithotripters are their durability, simplicity of use, and completely reusable components (Hofbauer et al, 1995). Adding to dependability are the successful fragmentation of all chemical stone composition

Ureteroscopy

Initially, ureteral stone fragmentation with EHL was performed before the ability to visualize the upper urinary tract directly was available. When scope technology allowed adequate visualization with a sufficient working channel, EHL became a viable option for stone treatment ([Goodfriend, 1984](#)).

The collateral damage of EHL causing ureteral perforations during lithotripsy was reported in early studies using blind, fluoroscopically guided probe positioning and unreported energy settings ([Goodfriend, 1984](#); [Watson et al, 1987](#)). In contrast, a series of 82 ureteroscopic cases using 2.4-Fr and 3.3-Fr probes through a 6.5-Fr semirigid ureteroscope reported no complications or perforations during lithotripter use and no strictures at 6 months ([Vorreuther and Engelking, 1992a](#)). In 99% of cases, probe-to-stone contact was made, and using adjustable energy settings (265 to 1382 mJ/pulse), the average pulse energy was 450 mJ, resulting in 90% success rates.

[Elashry and coworkers \(1996\)](#) performed a retrospective review of 45 patients failing extracorporeal shockwave lithotripsy (ESWL) who underwent EHL fragmentation. Performing 36 cases using

flexible ureteroscopes (and 1.9-Fr probe), 64% were middle pole and 17% were lower pole stones. Of cases, 98% were considered successful (fragments <2 mm on direct visualization). Lower pole stones were effectively treated in 94% of patients, and at the time, laser fibers were not flexible enough to achieve active deflection into the lower pole. Another study of 114 patients undergoing flexible ureteroscopy confirmed the effective lower pole fragmentation by EHL; no statistical difference was noted between intrarenal stones based on location, and overall stone clearance rate was 80% (which decreased to 50% for stones >2 cm) ([Dasgupta et al, 2004](#)).

Larger stones have been successfully treated with flexible ureteroscopy and EHL when combined with Ho:YAG laser. [Mariani \(2007\)](#) reported on 15 patients with stones 2 to 4 cm ([Kressel et al, 1992](#)) and 17 patients with stones greater than 4 cm. With up to four outpatient treatment sessions, endoscopic management included laser lithotripsy to weaken large stones and EHL to debulk the fragments. The stone-free (fragments <4 mm) rate was 90%, and no reports of perforations or follow-up strictures were noted. Although not the current standard of care for stones of this size, with improvements in flexible scope and probe technology, larger stone burdens are commonly being attempted ureteroscopically.

Bladder Stones

Cystolithotripsy was the initial application for EHL, and the reduced morbidity experienced with intracorporeal lithotripsy under direct vision was a major stepping-stone for endoscopy in urology. Although initial reports showed poor recurrence rates of bladder stones with EHL (50%) compared with vesicolithotomy (7.4%)

([Short et al, 1984](#)), very few complications were encountered. Since 1981, older patients were being treated, and cystolithotripsy was being combined with concurrent TURP ([Bülow and Frohmüller, 1981](#)). Because tip breakage and bladder perforations can still occur, it still must be used with caution ([Pelander and Kaufman, 1980](#); [Bülow and Frohmüller, 1981](#)).

(Teh et al, 1998) and the ability to use interchangeable probes to facilitate stone breakage anywhere in the genitourinary tract.

Probes are available in diameters of 0.8 mm (2.4 Fr), 1 mm (3 Fr), 1.6 mm (4.8 Fr), 2 mm (6 Fr), and 3.5 mm (10.5 Fr). In a head-to-head bench comparison of pneumatic (4.8-Fr probe, 2.5 bar), EHL (3-Fr probe, 80% power), laser (0.32-mm fiber, 100 mJ), and ultrasonic (4.5-Fr probe, power setting 3) lithotripters by Teh and colleagues (1998), fragmentation efficacy index (minutes/gram of fragmented stone) was compared. Pneumatic lithotripsy (5.00 ± 0.94 min/g) was the least efficient, whereas ultrasonic was the most efficient (8.49 ± 1.15 min/g), followed by laser (7.62 ± 0.78 min/g) and EHL lithotripters (6.60 ± 1.58 min/g). When increasing probe sizes at constant pressures (2 bar), incremental improvements in fragmentation were noted (3 Fr = 14 min/g, 6 Fr = 6 min/g). Pneumatic lithotripsy is effective in fragmenting harder stones and is less efficient in very soft stones; this is likely because the jackhammer effect produces numerous tiny fragments or because, in the case of extremely soft stones (i.e., matrix stones), the probe punches holes into stones without fragmentation.

Tissue Effects

A survival porcine model was used to test the short-term and long-term effects of 5- to 7-second bursts of LithoClast mucosal exposure to bladder and ureteric urothelium. A short duration was selected to simulate inadvertent contact experienced during stone fragmentation. Histologic changes in immediately sacrificed animals included focal areas of hemorrhage with mucosal erosions and transmural edema. At 3 and 6 weeks, the treated areas were unidentifiable, and histology failed to identify any significant changes. All animals experienced 24 to 48 hours of hematuria but failed to show any other systemic or diagnostic differences (Denstedt et al, 1995).

In a four-way comparison of intracorporeal lithotripters on iatrogenic urothelial trauma, Piergiovanni and associates (1994) found perpendicular exposure to pneumatic probes to be the least traumatic (compared with laser, ultrasonic lithotripsy, and EHL). Assessing perforation thresholds for each modality, at 250 pulses, the 0.8-mm probe perforated ureteric walls, whereas larger probes (1- and 2-mm probes) were unable to perforate the ureter or bladder, regardless of total number of pulses.

See the Expert Consult website for further details.

KEY POINTS: PNEUMATIC LITHOTRIPSY

- Pneumatic lithotripsy uses compressed air to drive a projectile forcefully against the probe tip, transmitting repetitive ballistic forces to the stone surface similar to a jackhammer.
- Causing limited mucosal erosions and transmural edema, pneumatic lithotrites cause the least amount of trauma compared with other intracorporeal lithotripters.
- The efficiency of stone fragmentation is improved by increasing probe diameter and pulse frequency independently.
- Stone migration is a significant disadvantage when treating ureteric stones with pneumatic lithotripsy.

Ultrasonic Lithotripsy

Ultrasonic lithotripsy affords a straightforward method of stone fragmentation, while simplifying extraction. Instead of manually extracting fragments after treatment, a central channel for suction provides simultaneous stone debris aspiration during lithotripsy. The most common applications at the present time are percutaneous nephrolithotomy and cystolithotripsy, although applications in ureteroscopy exist.

Basic Physics

Ultrasonic lithotrites pass electrical current through piezoceramic crystals, producing directional sound waves of 23,000 to 27,000 Hz.

The hand piece houses the piezoelectric interface, and waves propagate as mechanical vibrational energy longitudinally down a solid or metal probe to where contact is made with the stone (Segura and LeRoy, 1984). As the metal probe vibrates, when contact is made with the stone, this reverberation transmitted to the stone causes fracturing (Teh et al, 1998) along with the mechanical trauma of the oscillating metal tip against the surface (LeRoy and Segura, 1984). Solid metal probes disintegrate stones by transmitting mechanical energy in a transverse plane, rather than longitudinally as with hollow probes. Local fracture can produce fine debris, which is aspirated by the probe; or if the probe is applied to fault lines, regional breakage can be created leading to larger fragments.

Tissue Effects

Using an amplitude of 50 μ m, no perforations could be created in rabbit bladders. Edema and submucosal hemorrhages were caused when only suction was applied, and irrigation (20 mL/min) kept frictional heating to a minimum. Metal splinters were observed embedding into the bladder wall, but after 9 weeks, minimal inflammation was noted on histology (Stackl and Marberger, 1985).

Piergiovanni and coworkers (1994) compared the Olympus ultrasonic lithotripter with EHL, pneumatic, and Ho:YAG laser lithotripters to assess tissue effects on a porcine bladder. Ureteral and bladder perforations were impossible with perpendicular application of the ultrasonic and pneumatic probes. Histologic analysis immediately after application displayed denuded epithelial layers and edema.

When applied to immediately removed human renal pelvis samples (postnephrectomy), perpendicular application of suction alone caused 50% to 80% mucosal denudation, whereas the ultrasonic probe (21,000 Hz) caused 100% mucosal stripping, with no evidence of muscularis injury, regardless of application time (Khemees et al, 2013a). A case report from 1988 described symptomatic hyponatremia during cystolithotripsy using an ultrasonic lithotrite and distilled water with a resulting intraperitoneal perforation. Although this treatment is not common practice today, it highlights that clinical conditions may not always reflect animal or in vitro models, and caution should still be exercised (Batra et al, 1988).

See the Expert Consult website for further details.

KEY POINTS: ULTRASONIC LITHOTRIPSY

- Piezoceramic crystals produce directional sound waves of 23,000 to 27,000 Hz. Vibrational energy is transmitted from the probe tip to the stone surface, and fragment debris are aspirated through the central lumen of the tip.
- In vitro testing shows that direct contact with the urothelium causes mucosal stripping, although deeper perforations are difficult to achieve.
- Ultrasonic lithotripsy is useful in large soft stones; however, for harder stones, ultrasonic lithotripsy is most efficacious when paired with pneumatic lithotripsy in dual modality lithotrites.

Holmium:YAG and Erbium:YAG Laser Lithotripsy

See the Expert Consult website for details.

Basic Physics

Laser physics for tissue-based applications are discussed in detail in Laser Instrumentation: Soft Tissue Applications.

Early on, questions existed surrounding the mechanism of lithotripsy of holmium lasers. Preceding technologies, such as the ruby and Nd:YAG lasers, used photoacoustic or photomechanical processes, where light energy created shockwaves that fragmented

Ureteroscopy

Thin pneumatic probes, ranging from 0.8 to 1 mm, are easily accommodated by ureteroscopes and are commonly used for semirigid ureteroscopy. Because of the high safety threshold, fragmentation efficacy, and cost-effectiveness, it continues to be a popular modality. Comparing the shearing potential of four intracorporeal lithotripters on endoscopic baskets, **pneumatic devices are the only modality not to cut through wire** (Cordes et al, 2011). In ureteroscopy, where safety guidewires, trapped or hung baskets, and antiretropulsion devices may lie in close proximity to targeted stones, pneumatic lithotripters can provide an additional level of safety. Knowing that mucosal injury and wire damage are minimized with this technology may help provide confidence when aggressively treating difficult ureteric stones.

Probe size and pulse frequency settings can alter fracture efficiency. Even with the smallest diameter probes, hard stones can be fragmented through anterograde or retrograde ureteroscopy. An in vitro study using avian gut as a ureteric model examined the differing fragmentation rates of 5-mm phantom stones using different probes and settings. **Increasing probe diameter (0.8 to 1.6 mm) and pulse frequency (6 to 12 Hz) both independently decreased the total number of required pulses to treat the stones completely** (Shadpour et al, 2009).

Stone migration is a significant disadvantage when treating ureteric stones because the ballistic effect of the probe can propel stones in capacious ureters into the kidney. Retropulsion has been reported in 10% of distal and 40% of proximal stones treated with pneumatic lithotripsy (Knispel et al, 1998). If flexible instruments are not readily available, stones washed into the kidney may require secondary procedures (i.e., ESWL). The risk of fragment migration is related to site, degree of impaction, size, lithotripsy modality, irrigation system, and degree of proximal ureteric dilation (Delvecchio et al, 2000; Lee et al, 2003; Hendlin et al, 2008). Antiretropulsion strategies such as stone pinning (between probe and urothelium), reverse Trendelenburg positioning, basket stabilization, and proximal placement of lidocaine gel may be used. Specific antiretropulsion products include the Stone Cone (Boston Scientific, Marlborough, MA), N Trap (Cook Urological, Spencer, IN), Passport Balloon (Boston Scientific), Parachute (Boston Scientific), Accordion (PercSys, Palo Alto, CA), and BackStop (Boston Scientific). Developed for markets where flexible instrumentation is not feasible, these products may help reduce the risk of stone migration (Bastawisy et al, 2011).

A randomized controlled trial of Ho:YAG laser (365 μ m) and pneumatic lithotripsy (2.4-Fr probe) was performed in 79 patients undergoing semirigid ureteroscopy. Mean stone size was 12 mm, and most stones were located distally. Laser lithotripsy resulted in a superior stone-free rate at 1 month on radiographic and ultrasound follow-up (95% vs. 80.5%). Stone retropulsion was more common with pneumatic lithotripsy, and no significant complications were reported in either arm (Maghsoudi et al, 2008). A retrospective review of 500 patients treated during the period 1995-2002 showed that **stone-free rates are dramatically affected by stone position and size**. Stone-free rates for stones 10 mm or less were 97.1% for distal ureteric stones and 91% for proximal stones. For stones greater than 10 mm, distal stone-free rates were 89% for distal stones and 71.4% for proximal stones (Sözen et al, 2003). With a 6.4% overall complication rate, only 1.4% of patients developed mucosal injuries or perforations as a result of probe use.

Two series highlighted the safety of pneumatic lithotripsy in pregnant women with symptomatic ureteral stones (Hoşcan et al, 2012; Abdel-Kader et al, 2013). In both reports, the mean gestational age at presentation was 25 to 26 weeks, and most stones were located in the distal ureter. Using semirigid ureteroscopy, a stone-free rate of 85.3% to 100% was reported with no major anesthetic, surgical, or obstetric complications (Abdel-Kader et al, 2013). One patient developed premature contractions, which did not progress to early labor.

Ideally, a semirigid ureteroscope with a straight end on working channel should be used for pneumatic stone treatment

because bending pneumatic probes reduce the transmitted energy from the generator to the stone (Grocela and Dretler, 1997). Although 2.4-Fr probes are flexible and can be accommodated by flexible ureteroscopes, an analysis by Zhu and coworkers (2000) quantified the energy loss secondary to probe bending. By measuring tip mechanics, impact momentum decreased 50% and energy by 76% when probe tips were deflected 33 degrees. With 48 degrees of deflection, only 30% of full fragmentation efficiency could be achieved.

Bladder Stones

Transurethral (Teh et al, 1998; Khosa et al, 2012; Rabani, 2012) and percutaneous (Agrawal et al, 1999; Wollin et al, 1999) **pneumatic lithotripsy have been found to be useful in large hard stones such as calcium oxalate monohydrate and cystine stones** (Denstedt et al, 1992). A retrospective series comparing ultrasonic, pneumatic, and mechanical lithotripsy for bladder stones showed equal efficacies for stones less than 3 cm (Razvi et al, 1996).

Khosa and colleagues (2012) reported a series of 100 children younger than 15 years old from Pakistan who underwent pneumatic cystolithotripsy using a 4-Fr "mini-scope" or a 7/8.5-Fr ureteroscope for bladder stones less than 3 cm. The average patient was 5 years old, and all surgeries were performed as outpatient procedures. Only 5% of patients developed hematuria, and one experienced postoperative urinary retention.

Cases of calcified foreign bodies such as encrusted ureteric stents (Grocela and Dretler, 1997) and eroded transobturator tapes (Osório et al, 2011) have been treated with pneumatic lithotripsy. An advantage of this modality with retained stents is that pneumatic lithotripters can be applied safely in transurethral or percutaneous cystolithotripsy, ureteroscopy, and percutaneous nephrolithotomy. Also, when stones abutted against the urothelium need to be fragmented, pneumatic lithotripsy is safe to make contact with the urothelium for short periods of time.

Single setting TURP and percutaneous or transurethral pneumatic lithotripsy have been reported as treatments in patients in whom outlet obstruction is the precipitating cause of bladder stones (Sinik et al, 1998; Aron et al, 2007). Stone removal is performed initially, and if a percutaneous approach is used, the working sheath is maintained until after TURP to reduce the risk of extravasation. In a comparative analysis of patients undergoing either percutaneous or transurethral lithotripsy with simultaneous TURP, the percutaneous approach (using a 30-Fr sheath) decreased stone removal time by 45% and the need for secondary procedures (Tugcu et al, 2009). Patients who underwent purely transurethral procedures had their catheters removed earlier (2.2 days vs. 3.2 days) and had shorter admissions (1.2 days vs. 2.3 days); however, three patients (7.9%) developed subsequent urethral strictures.

Percutaneous Nephrolithotomy

Similar to treatment of bladder stones, percutaneous nephrolithotomy allows the use of larger scopes and larger probes. A Canadian trial comparing the StoneBreaker (Cook Urological, Spencer, IN) with the Swiss LithoClast showed improved fragmentation times, reduced setup time, and decreased user fatigue with the StoneBreaker. No differences in stone-free rates or complications were noted. The LithoClast uses medical air and requires a pedal for activation, whereas the lighter weight StoneBreaker uses a CO₂ cartridge, is triggered by hand, and produces 10 times the impact pressure. Because pneumatic lithotripsy is valuable in large and hard stone compositions, it has been combined with ultrasonic lithotripters to improve on the advantageous characteristics of both modalities (see later). The Clinical Research Office of the Endourological Society reviewed 5800 percutaneous nephrolithotomy procedures (from 96 centers) to assess success rates based on mean Hounsfield units and various surgical characteristics. On regression analysis, pneumatic lithotripsy showed the highest probability of stone-free status (90%) even when compared with combination ultrasonic/pneumatic modalities (82%) (Anastasiadis et al, 2013).

Ureteroscopy

The first clinical series reporting the use of ultrasonic lithotripsy comprised 412 patients treated for bladder stones in 1984. Probe diameters range from solid 2.5-Fr probes (for semirigid ureteroscopy) to 6.0-Fr used for cystoscopy and nephroscopy. Several bladder stone series corroborate the low complication rates and high success rates for stones of varying sizes using transurethral and suprapubic approaches (Cetin et al, 1988; El Khader et al, 1995; Razvi et al, 1996). A review of 176 patients undergoing bladder stone surgery during the period 1976-1994 noted an 88% success rate for ultrasonic lithotripsy, failing with “very hard stones” (Razvi et al, 1996).

Ureteroscopic fragmentation using ultrasonic probes was slower to gain popularity because of the required advancement in ureteroscopic technology and reduced probe sizes (2.5 to 4.5 Fr) required. With 2.5-Fr “solid wire” probes, a central lumen for aspiration is impossible. Some flexibility can be achieved for applications requiring active deflection during flexible ureteroscopy. Because EHL, pneumatic lithotripsy, and laser lithotripsy gained popularity around the same time as solid wire probes were developed, ureteroscopic applications of this technology never reached the same popularity as use of the technology in upper and lower tract indications (Gur et al, 2004). Preliminary reports documented flexible ultrasonic probes used through fiberoptic flexible scopes resulting in an 87.5% success rate in 16 patients (Higashihara and Aso, 1989).

Pedro and Netto (2008) compared ESWL with ultrasonic lithotripsy in 235 consecutive patients with proximal ureteric stones with near-equal efficacy (85.6% ultrasonic lithotripsy vs. 90% ESWL success rates) and no differences in complication rates and mean procedure times. A review of all semirigid ureteroscopic ultrasonic series by Gur and coworkers (2004) identified 9 studies from 1983-1999 ranging from 7 to 311 patients. Pooled analyses of 863 patients identified an overall fragmentation rate of 89%, perforation rate of 2.5%, and “other complications” rate of 3.8% (including strictures, avulsions, sepsis, and false passage formation).

Percutaneous Surgery

Applications in percutaneous surgery closely followed cystolithotripsy, and by the mid 1980s, ultrasonic lithotripsy was being applied to percutaneous renal surgery (Segura and LeRoy, 1984). Used in pediatrics, horseshoe kidneys (Holman et al, 1986), and total staghorn calculi (Rodrigues Netto et al, 1988), ultrasonic

lithotripsy has been a versatile tool in percutaneous surgery. In approaches ranging from anatomic nephrolithotomy to percutaneous surgery, ultrasonic fragmentation was found to reduce operating times (from 210 minutes to 120 minutes), admission times (from 7 days to 5 days), and secondary interventions (from 50% to 20%), with a much earlier return to normal physical activity (43 days vs. 9 days) (Rodrigues Netto et al, 1988).

Newer combined technologies have improved on the fragmentation capabilities of ultrasonic lithotripsy by combining it with pneumatic lithotrites (see later). Dual modality fragmentation with combined ultrasonic lithotripsy and pneumatic lithotripsy showed improved stone-free rates (92% vs. 85% ultrasonography alone), fewer secondary procedures, and decreased operative times, without an increase in complication rates (Cho et al, 2010). With regard to harder stones, a prospective randomized trial assessing 30 patients with cystine, calcium oxalate monohydrate, or calcium phosphate stones showed a clear advantage for combined fragmentation, whereas softer stones had more favorable results with the ultrasonic lithotripter alone (Lehman et al, 2008).

Because contact must be made between the probe and stone, drilling or painting motions are used to trap the stone between urothelium and the probe. Smaller stones may be brought to the probe and held in place with suction alone. Continuous irrigation helps improve visualization, decrease heat buildup, and wash stone debris through the probe. When soft stones (e.g., struvite) are encountered, complete fragmentation and suction removal of the stone may be facilitated with ultrasonic lithotripsy. For harder stones, a drilling technique can be used to fracture the stone into manually extractable stones.

Larger pieces can be fragmented further or extracted manually. **Using continuous irrigation and suction keeps the probe tip cool, while continuously removing particles (Hofmann et al, 2002).** As the fluid is evacuated through the hand piece, it cools the piezoceramic crystals, which can rapidly increase in temperature if proper suction is not maintained. Without adequate suction, in addition to a noticeably hot hand piece, visualization and stone clearance are impeded. It is important to tailor suctioning to the irrigation rate during probe activation; otherwise, air can be introduced when aspiration outpaces irrigation inflow, obscuring the field with bubbles. This situation can be avoided by reducing the suction pressure, increasing irrigation height (or pressure), or intermittently clamping the suction tubing to allow enough fluid to remain in the renal pelvis/bladder for distention and visualization.

Holmium:YAG lasers have revolutionized kidney stone management and flexible ureteroscopy. In conjunction with improved optical systems in actively deflecting ureteroscopes, all areas of the genitourinary tract are now safely accessible for endoscopic lithotripsy using these lasers. Preliminary testing of the erbium:YAG

(Er:YAG) laser showed improved fragmentation efficiency of kidney stones compared with the Ho:YAG laser. Producing larger fragments with a smaller soft tissue penetration depth, this technology holds promise for future application in endourology.

stones. In contrast, photothermal stone breakage during holmium laser use was hypothesized based on early observations of “glowing hot stones.” Photothermal processes involve direct light energy absorption (“photo”) by stone surfaces causing rapid temperature (“thermal”) increases, before significant heat diffusion can occur.

Using a combination of techniques, **Chan and colleagues (1999)** identified the predominant mode of Ho:YAG lithotripsy to be photothermal. Mass loss experiments showed less fragmentation when stones -80°C were treated. As expected with a thermal mechanism, more energy was required to increase temperatures to ejection thresholds when starting below physiologic temperatures. After treatment, chemical analysis of all stone types showed thermal breakdown components. Finally, synchronized photography failed to identify fragmentation during bubble expansion or collapse, and measured pressures were too low (2 to 20 bar) to induce fracture.

Ablation crater volumes are associated with the irradiated surface photon density (fluence) and pulse energy. A “Moses effect” occurs by the rapid vaporization of fluid creating a vapor channel between the fiber tip and stone surface, allowing for more direct energy transfer. Although photoacoustic forces are not thought to contribute to fracture, interstitial water vaporization is likely involved with fragment ejection. Tensile and compressive forces, which dictate Nd:YAG lithotripsy, ESWL, and EHL, are not important (**Chan et al, 1999**).

Ho:YAG lasers produce fine fragments in large part owing to photothermal energy absorption by urolithiasis; this results in the breakdown and disintegration of the heated area, causing craters and fragmentation (**Qiu et al, 2010**). As a result of the relatively long pulse rate (250 to 350 μsec), the Ho:YAG laser is considerably less efficient than other shorter pulse lasers. Because Er:YAG lasers have a shorter pulse duration and longer wavelength (2940 μm), they can still produce small fragments, but with improved efficiency over Ho:YAG lithotripsy.

The Er:YAG laser uses optical energy, and similar to Ho:YAG, irradiation of the stone’s surface leads to increasing temperatures. Er:YAG lasers produce a 2940-nm wavelength, which has a fivefold increase in photothermal absorption by urolithiasis. Although shockwave production is insufficient for stone breakage in Ho:YAG lasers, Er:YAG lasers also show improved photoacoustic vapor bubble force transmission. With higher acoustic transients, the Er:YAG laser forms a torpedo-shaped vapor bubble in the interfacing fluid between probe and stone. The vapor bubble of the Ho:YAG laser is pear-shaped, leading to increased energy loss laterally, producing weak shockwaves with minimal effect on stone fracture.

The radiant threshold for Er:YAG to initiate lithotripsy is 0.47 J/ cm^2 at 2940 nm for calcium oxalate monohydrate compared with a Ho:YAG threshold of 7.36 J/ cm^2 . Deeper craters and larger ablation volumes are produced at this wavelength (**Lee et al, 2006**). The combination of effective photothermal and photoacoustic lithotripsy of Er:YAG leads to faster fragmentation, with larger subsequent pieces. In vitro studies showed larger fragments are created by Er:YAG; however, calcium oxalate monohydrate and cystine stone lithotripsy resulted in fragments less than 1 mm for both lasers, which clinically would be considered equivalent. Soft tissue depth of penetration is 0.79 μm , which is a significant improvement in safety compared with Ho:YAG (0.5 to 1 mm).

A problem with Er:YAG laser technology is that the hydroxy silica quartz fibers used in Ho:YAG machines are not compatible. Although sapphire fibers used with Er:YAG are too brittle and thick to be used in routine endourologic procedures, salivary stones were treated in wet-field applications using semirigid instrumentation (**Raif et al, 2006**). ZBLAN fluoride glass fibers have favorable properties in regard to reflection losses and light attenuation. However, because of a much lower melting point, durability is inadequate for clinical use. Before this technology can be applied to kidney stones, improved mechanical, thermal, and chemical fiber reliability is required. Hybrid fibers using fluoride cores with sapphire protection tips and circumferential cladding may help provide the transmission and flexibility required for endourology (**Qiu et al, 2010**).

See the Expert Consult website for further details.

A technique dubbed “popcorning” uses both the photoacoustic and the photothermal mechanisms of laser lithotripsy. **Photoacoustic and photothermal properties of a laser are functions of pulse duration and energy. Longer pulse duration produces greater photothermal functionality.** Although most Ho:YAG lasers have fixed durations of 250 to 350 μm , adjustable units are becoming more common. Shorter pulses yield higher peak power in resulting shockwaves. In a ureteric model, increasing pulse duration from 300 to 700 μm reduced stone retropulsion by 50% (**Finley et al, 2005**). Pulse duration is inversely related to power and can manipulate stone motion depending on the circumstance; this can be helpful in difficult-to-reach anatomy (i.e., lower pole stones) or when numerous fragments exist in a confined area (i.e., minor calyx). The fiber tip is placed several millimeters away from the stones (and mucosa), and shockwaves produced by vapor bubbles collapsing cause stones to bounce like popcorn. As stones are agitated, intermittent contact with the laser fiber causes photothermal disintegration. As time passes, the “popcorning” effect continues to produce smaller and smaller fragments, resulting in a fine stone dust, which is passed without consequence. An in vitro experiment identified settings of 1.0 J and 20 Hz as giving the most efficient fragmentation when using this technique (**Chawla et al, 2008**).

See the Expert Consult website for further details.

KEY POINTS: HOLMIUM:YAG LASER LITHOTRIPSY

- Laser lithotripsy has brought versatility to intracorporeal lithotripsy by allowing safe fragmentation in virtually all areas of the genitourinary tract.
- Ho:YAG laser fragmentation is predominantly due to photothermal decomposition and possibly photoacoustic propulsion of fragments.
- Laser output can be adjusted based on rate (Hz), energy (J), pulse duration (μsec), and fiber size (μm).
- Maximal deflection is achieved with 200- μm fibers during flexible ureteroscopy; however, maximal efficiency is seen with 360- μm fibers.
- Proper laser fiber handling can help reduce scope damage and prolong the life of reusable fibers.
- Techniques used during stone fragmentation include painting and “popcorning,” which create fine stone dust (precluding removal), or crude fragmentation for basket extraction.
- Laser lithotripsy can produce the smallest fragments and is efficacious in all stone compositions.

Dual Modality Lithotripters

Newer modalities have been developed by combining ultrasonic and pneumatic lithotripters into a single hand piece. The Swiss LithoClast Ultra and CyberWand (Olympus, Southborough, MA) use different strategies to capitalize on the advantages of each modality. Pneumatic lithotripsy is effective at fragmenting harder stones, whereas ultrasonic action produces smaller fragments, while simultaneously removing them from the field. These hybrid systems are available only as rigid probes and can be used only in transurethral or percutaneous procedures (**Fig. 11-5**).

LithoClast Ultra

The LithoClast Ultra was the first dual modality lithotripter, combining two independently functioning hand pieces that are fixed together. **The front piece houses the ultrasonic lithotripter, with a central channel allowing throughway for the slender pneumatic probe.** The 1-mm solid pneumatic probe sits within the suction channel of the 3.3-mm hollow ultrasonic probe. Fine-tuning of positioning of the pneumatic probe tip (relative to the ultrasonic tip) can be achieved using the depth wheel built into the hand piece. Pneumatic activity can be triggered as needed or continuously

Ureteroscopy

By reducing the diameter of ureteroscopes, slender intracorporeal lithotripters must pass easily through a working channel smaller than 4 Fr, while allowing room for irrigation. These instruments also must be durable enough to be advanced and retracted repeatedly through a scope without breaking, even when deflected 270 degrees. Ho:YAG laser lithotripsy fulfills these requirements because hydroxy silica fibers are thin, flexible, and durable and possess transmission efficiencies allowing for effective photothermal stone fragmentation.

Flexible ureteroscopy typically uses 200- μ m laser fibers, which have a minimal impact on scope deflection. For semirigid ureteroscopy, 365- μ m fibers are more suitable, although they can be used with flexible nephroscopy if minimal deflection is required (i.e., upper pole stones). These are considered workhorse fibers because they have been shown to display maximal efficiency and durability while being typically cheaper (than 200- μ m fibers) (Kuo et al, 1998).

Laser fiber tips should be advanced until clearly visualized by the operator (several millimeters past the lens). During flexible ureteroscopy, this may become problematic for lower pole stones because fiber advancement can damage the scope liner or optics or fracture the fiber itself. If a fractured fiber is used while in a scope, catastrophic damage and costly repairs can result. Fiber advancement should be performed with the scope tip in neutral

position and then actively deflected to the area of interest. Newer fibers (i.e., Flexiva TracTip [Boston Scientific, Marlborough, MA]) have been created with a carved bulbous tip, theoretically allowing the fiber to pass through an already deflected scope without damage. The cladding helps permit high energy transfer even when bent, and using a 240- μ m core, it is rated to handle settings up to 50 W. In an analysis of 96 clinically used fibers, none were broken. Bench testing revealed only a loss of 5 degrees of ureteroscopic active deflection (U-500 flexible ureteroscope [Stryker Endoscopy, San Jose, CA]; from 275 degrees to 270 degrees) (Khemees et al, 2013b). Alternatively, for stone repositioning from difficult-to-reach areas to the upper pole, using endoscopic baskets may help reduce the need for prolonged extreme deflection.

Ureteroscopic laser fragmentation can be performed by several techniques. Dust-sized fragments are produced by painting the fiber across the surface of a stone. Avoiding the creation of large fragments that are difficult to pass makes basket extraction unnecessary. By using lower energy levels of 0.2 J and higher pulse rates (i.e., 40 Hz), small debris and minimal retropulsion are encountered, while trading off a reduction in total fragmentation. Controlling for total energy, increasing pulse energy levels were found to result in larger fragments, with faster fragmentation times. Alternatively, as laser fragmentation becomes more time-consuming as fragments become smaller, one can create large pieces and remove them using an endoscopic basket.

With improving endoscopic technology, ureteroscopy and intracorporeal lithotripsy have replaced ESWL for treatment of many ureteric stones. A review of 82 patients undergoing either ESWL or ureteroscopy for impacted proximal stones showed no difference in 3-month stone-free rates (80% vs. 68%) or complications, although patients undergoing ESWL required more secondary procedures (Khalil, 2013). Similar results were achieved in a prospective randomized trial comparing 180 patients undergoing ESWL or semirigid ureteroscopy and laser lithotripsy for stones less than 2 cm. No significant differences were found between the two modalities in terms of 3-month stone-free rates, although re-treatment rates were higher for ESWL (6.1% vs. 1.1%, $P < .001$) (Kumar et al, 2013). In contrast, a multicenter randomized trial of distal and mid-ureteric stones ($n = 156$) treated with ESWL or ureteroscopy and laser lithotripsy showed an advantage for ureteroscopy. The 3-month stone-free rate was 91% for ureteroscopy (vs. 51% for ESWL), and re-treatment rates were significantly lower (9% vs. 45% in ESWL) (Hendriks et al, 1999). Several authors found cost savings associated with ureteroscopy and laser use compared with ESWL because of higher success rates and lower re-treatment rates (Parker et al, 2004; Cone et al, 2014). Laser lithotripsy had lower initial (\$7575 vs. \$9507) and total (\$9378 vs. \$15,583) charges.

Comparing other intracorporeal lithotripsy modalities, a retrospective review of 394 patients with proximal ureteral stones treated with laser or pneumatic lithotripsy via semirigid ureteroscopy was performed showing 86% were treated successfully with pneumatic lithotripsy; 14% required secondary ESWL for residual fragments (identified on radiograph). Laser lithotripsy produced a 97% stone-free rate, and only 2% required secondary procedures. Ureteral perforations were uncommon and not significantly different between groups (Bapat et al, 2007). In larger distal and mid-ureteric stones (mean diameter 13 mm), a prospective randomized trial showed a delayed stone-free rate of 95% with laser lithotripsy versus 85% with pneumatic lithotripsy on noncontrast computed tomography. Laser use was associated with less stone migration, although complication rates were for both arms (Kassem et al, 2012).

Stone position plays a large part in the success rates of ureteroscopy and laser lithotripsy. In a retrospective study, 272 patients undergoing flexible ureteroscopy from 2002-2006 and laser lithotripsy for renal stones were found to have an overall stone-free rate of 94% on follow-up noncontrast computed tomography. Stone-free rates were best for upper pole stones (100%), followed by middle pole stones (95%) and lower pole stones (90%), although not significantly different ($P = .338$). Similarly for the ureter, stone-free rates decreased from distal ureteral (96.8%) to proximal ureteral (79.4) stone location. Complication and re-treatment rates were significantly higher with proximal stone location (Seitz et al, 2007).

Effective fragmentation using laser lithotripsy can be accomplished for any chemical stone composition, although efficiency is decreased with harder stones. Maintaining consistent power settings, magnesium ammonium phosphate stones are the most readily fractured, followed by calcium hydrogen phosphate dehydrate, cystine, uric acid, and calcium oxalate monohydrate. Increasing energy improves fragmentation for all stone types (Teichman et al, 1998). The differences are partly related to the melting points of the various stones as well as the vapor-surface interface. However, after reviewing ureteroscopic procedures performed on 86 renal and 101 ureteral stones, Wiener and colleagues (2012) failed to show any differences in operating room time related to stone composition. Perhaps owing to active fragment removal using endoscopic baskets, coarse fragmentation techniques may not be as sensitive to chemical composition. Instead, if disintegrated to stone dust, one could hypothesize that harder stones would require more time.

Because of its relatively high safety profile, laser lithotripsy has been applied to children (Fraser et al, 1999; Yeow et al, 2009), patients with bilateral stones (Huang et al, 2012; Atis et al, 2013), and patients with anatomic abnormalities (i.e., horseshoe kidney, duplicated systems, transplant grafts) (Molimard et al, 2010; Hyams et al, 2012). Ureteroscopy and laser use have been found to be safe in a retrospective review of 25 anticoagulated patients. Semirigid (6.9-Fr probe) and flexible (7.5-Fr probe) ureteroscopy was

performed, and basket extraction was avoided by dusting all stones. Distal ureteral dilation (8/10-Fr coaxial dilator, balloon dilator, 14-Fr ureteric access sheath) was performed in 11 patients, and stents were placed in all patients after the procedure. Stone-free rates were 96% (100% distal ureter and mid-ureter, 89% proximal and intrarenal locations). For lower pole stones, upper pole repositioning was performed. No cases of significant bleeding or early termination secondary to bleeding were reported with laser use. Similar findings were reported in children with von Willebrand disease (Christman et al, 2012) (Fig. 11-4).

Up-front and disposable costs for laser lithotripters may be an issue for some hospitals. Because of the versatility of the Ho:YAG laser, it can be used not only in all parts of the genitourinary tract but also for interventions not involving stones. Reusable laser fibers allow a significant cost savings; one study from two hospitals showed a savings of more than \$64,000 by using 37 fibers (varying manufacturers and sizes) for 540 semirigid and flexible ureteroscopy cases (Knudsen et al, 2011).

Percutaneous Nephrolithotomy

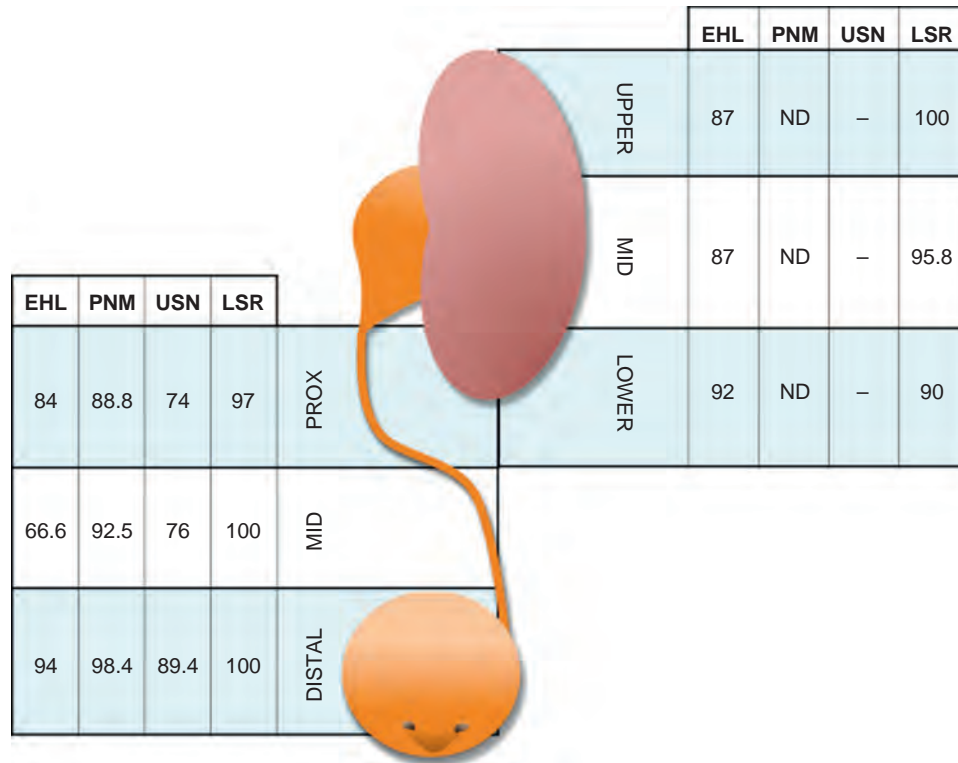

Although laser lithotripsy is not the favored modality for use in large renal stone burdens treated percutaneously, it plays an important role in flexible instrumentation. Anterograde nephroscopy using flexible scopes can access calyces that rigid nephroscopes cannot reach, reducing the need for multiple accesses. For patients with large impacted ureteric stones, reimplanted ureters, and reconstructed bladders, anterograde flexible ureteroscopy and laser lithotripsy can allow straightforward access to the stone. Coarse fragmentation and basket extraction simplify the procedure because the ureteric portion proximal to the obstruction is often dilated, allowing for active retrieval of larger stones.

Laser fragmentation is central to percutaneous nephrolithotomy performed with reduced-diameter sheaths (i.e., minipercutaneous, ultra-minipercutaneous, micro percutaneous). Developed initially for pediatrics, the procedure is now used in adults with sheath diameters ranging from 24 Fr (8 mm) to 16 gauge (1.3 mm). When using extremely narrow sheaths, techniques require special miniaturized imaging technologies and laser lithotripsy. Because stone extraction is impossible with extremely narrow sheaths, 200- μ m laser fibers are used to dust stones, and debris is cleared by pressurized irrigation or passive urine flow. Indications have yet to be clearly defined; however, studies comparing efficacy with flexible ureteroscopy, standard percutaneous nephrolithotomy, and ESWL have been performed. A randomized study comparing flexible ureteroscopy and micro percutaneous nephrolithotomy (16-gauge "all-seeing needle" and 272- μ m laser fiber) was performed in 70 patients for stones less than 1.5 cm. Equivalent stone-free rates, complication rates, and length of stay were identified. Increased pain scores (1.9 vs. 1.6, $P = .046$), analgesic requirements, and hemoglobin loss (0.96 g/dL vs. 0.56 g/dL, $P < .001$) were observed in the minipercutaneous nephrolithotomy arm. All patients had ureteric access sheaths placed, although 40% fewer patients required stent placement in the minipercutaneous nephrolithotomy arm (20% vs. 60%) (Sabnis et al, 2013).

Bladder Stones

In 1978, Fair reported the benefits of using a ruby laser to produce "stress pulses," which were able to fracture stones of any color, shape, size, hardness, and composition (Fair, 1978). Since then, Ho:YAG has become a useful option in transurethral and percutaneous approaches. In larger stone burdens, laser may not be the first choice; however, many still prefer laser cystolithotripsy because of its safety and ease of use.

With larger stones, the degree of fragmentation and stone dust produced by laser lithotripsy can reduce efficiency and visualization and increase operating room time. Combining lithotripter modalities and approaches in patients with stones greater than 4 cm may help reduce operative time and improve visualization and stone clearance (Sofer et al, 2004). The combination of laser

	EHL	PNM	USN	LSR

DISTAL	94	98.4	89.4	100

Figure 11-4. Stone-free rates (percentage) for intracorporeal lithotripters used in ureteroscopy by anatomic region. EHL, electrohydraulic lithotripsy; LSR, laser; ND, no data; PNM, pneumatic; PROX, proximal; USN, ultrasonic.

and ultrasonic lithotripsy allows for fragmentation of hard stones, while suctioning fragments and improving visualization. A combined percutaneous and transurethral approach can also improve flow and allow larger fragment removal and stone manipulation by two surgeons simultaneously without increasing complication rates (Sofer et al, 2004). Use of a 24-Fr scope through a 30-Fr Amplatz sheath (Cook Urological, Spencer, IN) placed through the urethra (with or without urethral dilation) has been reported to improve irrigation drainage, visualization, and stone localization during laser lithotripsy in female (Ramanathan, 1999; Kawahara et al, 2012a) and male (Okeke et al, 2004) patients.

Total stone burden (volume and area on noncontrast computed tomography) was the only variable found to correlate with total procedural time required for laser cystolithotripsy. Using 550- μ m laser fibers (100-W laser, set between 1.5 and 3.5 J, 5 Hz), cystolithotripsy was performed through a 26-Fr resectoscope. Stone hardness (measured by Hounsfield units and chemical stone composition) did not appear to affect operating room time significantly. Male gender added procedural time, although lithotripsy time was not significantly different between sexes (Kawahara et al, 2012b).

An advantage of laser cystolithotripsy is its use in flexible cystoscopy, allowing for treatment in reconstructed bladders and challenging genitourinary anatomy that precludes use of rigid instruments. Flexible laser lithotripsy has been used under local anesthetic in healthy men with stones greater than 3 cm, with minimal pain and improvements in lower urinary tract symptoms, without significant complications (Kara et al, 2009).

In pediatric urolithiasis, instrument diameter plays a key role in management options. Bladder stones have been successfully treated using 8-Fr ureteroscopes with 550- μ m laser fibers for stones less than 4 cm (Ramakrishnan et al, 2005). No laser-related complications were encountered perioperatively, and no children showed recurrences or urethral stricture formation in long-term follow-up (mean 48 months). In children with complicated genitourinary reconstructions, augmentations, and continence procedures, percutaneous laser cystolithotripsy through a previous suprapubic catheter site allowed for maximal stone fragmentation, while minimizing the risk to intraperitoneal structures and/or vascular supply to bowel segments used for augmentation (Cain et al, 2002).

When indicated, concomitant treatment of bladder stones and BPH has been reported using several modalities of prostatic resection, including green light laser (De la Torre et al, 2012), HoLEP (Shah et al, 2007), and TURP (Philippou et al, 2011), without significantly increasing the rate of complications. Bladder calculi are treated first so as to avoid injuring the resection bed after prostatic surgery or risk leaving stones behind should the procedure be terminated early. Rare cases of prostatic stones causing lower urinary tract symptoms and bladder outlet obstruction can also be treated with laser lithotripsy. Using a 550- μ m laser fiber (1 to 1.5 J, 15 to 20 Hz) through a rigid cystoscope, Goyal and colleagues (2013) reported complete stone removal resulting in improved International Prostate Scoring System scores and improved peak flow rates at 3 months. Concurrent laser urethrotomy can be performed if necessary.

Figure 11-5. Dual modality lithotripter configurations.

from 2 to 12 cycles per second. The ultrasonic probe can be adjusted based on power and duty cycle. A composite pedal allows selective or combined use of each modality. Three cords attach to the hand piece for medical air, ultrasonic power, and suction. In-line suction allows continuous fragment removal and collection (using a stone trap) and hand piece cooling.

For maximal control, the tip of the pneumatic probe should be slightly recessed from the outer ultrasonic probe. In this way, the ultrasonic probe can make maximal contact with the stone surface, and pneumatic retropulsion is limited. When activated, the pneumatic tip advances and strikes the stone beyond the ultrasonic probe tip. If large immobile stones are being treated (i.e., staghorn calculi), better fragmentation can be achieved by adjusting the pneumatic probe 2.5 mm past the ultrasonic sheath; however, simultaneous treatment of smaller fragments may become more challenging (VonDerHaar et al, 2010).

CyberWand

The CyberWand uses an ultrasonic hand piece producing vibrational energy by means of a piezoceramic crystal. Disposable probes are made of an inner 2.77-mm and outer 3.75-mm cylindrical metal tube. The inner probe screws onto the handset extending 1 mm past the tip of the outer sheath. The fixed inner probe vibrates at a frequency of 21,000 Hz. Owing to a free mass washer and dampening spring, the free-floating outer probe vibrates at approximately 1000 Hz, oscillating longitudinally 1 mm. Selecting “large stone” on the foot pedal couples both sheaths. **Ultrasonic energy from the inner sheath is transmitted to the outer, which moves in a ballistic manner, similar to pneumatic lithotripters (Auge et al, 2002).** The “small stone” pedal allows for finer control and activates only the ultrasonic action of the inner probe. The hollow lumen of the inner sheath of the probe incorporates irrigation suction, which simultaneously clears stone debris during fragmentation, while cooling the hand piece.

Noise levels related to CyberWand fragmentation (93 dB) were determined to be the loudest (at ear level) compared with the Storz Ultrasonic lithotrite (Storz, El Segundo, CA; 77 dB), Olympus LUS-2 single modality ultrasonic lithotripter (Olympus, Southborough, MA; 68 dB), and Ho:YAG laser (60 dB). If used for more than 90 minutes per day, only the CyberWand is above the threshold set by the U.S. Department of Labor and Occupational Health and

Safety Administration for risk of noise-related occupational hearing loss (Soucy et al, 2008).

Tissue Effects

Using fresh human urothelium from nephrectomy specimens, perpendicular application of the CyberWand and LithoClast was done for 2 to 8 seconds. Tissue effects were compared with untreated areas and control specimens (suction-only probe contact). Suction alone showed 50% to 80% denudation of urothelium, with no changes identified in the subepithelial or muscular layer. The CyberWand “small stone” setting showed 100% urothelial denudation, with separation of the subepithelial connective tissue layer and no muscular damage. During use with the “large stone” setting, a greater amount of subepithelial edema and muscular rupture was noted with increasing contact time to the mucosa.

For ultrasonography-only settings, the Swiss LithoClast Ultra and CyberWand (“small stone” setting) showed 100% urothelial denudation, with separation of the subepithelial connective tissue layer and no muscular damage. With 2 seconds of exposure, minimal tissue damage was noted. **Increasing contact time led to increased mucosal denudation and submucosal vacuolation. Muscle rupture worsened with increasing exposure times except for the single modality “small stone” setting on the CyberWand, which was unable to cause muscle rupture.** Based on these findings, the authors concluded that both modalities were safe, although contact time when using dual modality settings should be minimized when possible (Khmees et al, 2013a).

Clinical Use

Several studies showed the combination of pneumatic and ultrasonic lithotripters is more efficient compared with pneumatic or ultrasonic lithotripsy alone. Each modality separately cleared phantom stones 3.8 times (pneumatic) and 1.7 times (ultrasonic) slower than combination lithotripsy with the Swiss LithoClast Ultra (Soucy et al, 2008). An in vitro experiment using gypsum stones was performed to compare penetration times of the CyberWand and Swiss LithoClast Ultra. Penetration times were 41% shorter with the CyberWand with no significant differences in overheating, blockages, or malfunctioning (Kim et al, 2007).

See the Expert Consult website for further details.

Clinical use was assessed by randomly assigning 20 patients to either ultrasonic or combined modality lithotripsy during percutaneous nephrolithotomy. Combination lithotripsy reduced fragmentation time from 43.7 minutes to 21.1 minutes ($P = .036$), with slightly improved complication and stone-free rates (Pietrow et al, 2003). To compare the clinical efficacy between dual modality lithotrites, 138 patients with staghorn calculi were randomly assigned to either CyberWand or Swiss LithoClast Master fragmentation. Although shorter operative times were encountered with CyberWand allocation (77.1 minutes vs. 84.3 minutes, $P = .049$), no differences in stone clearance or complication rates were noted (Li et al, 2013).

Surgical technique during treatment can affect efficiency of stone fracture. Applying force to a hand piece against a stone can improve or reduce fragmentation efficacy. The rate of stone mass removal

was measured in an in vitro analysis using 400g, 1000g, and 2000g of in-line force on a CyberWand and Swiss LithoClast Ultra hand piece. For the CyberWand dual modality settings, 400g and 1000g were significantly more efficient than 2000g, whereas with ultrasonography alone (on the Swiss LithoClast), efficiency increased with pressure and rotation of the probe by 90 degrees. This study also corroborates the improved fragmentation of the CyberWand against all settings of the Swiss LithoClast (Goldman et al, 2009). Too much pressure on the CyberWand may impede the movement of the outer low-frequency probe, leaving fragmentation to occur only with the ultrasonic action of the inner probe. However, the LithoClast Ultra functions better at higher pressures and with rotation. Because both the pneumatic and the ultrasonic components are actively driven by separate mechanisms, applying pressure does not prevent movement, as in the CyberWand (Goldman et al, 2009).

KEY POINTS: DUAL MODALITY LITHOTRIPTERS

- Dual modality lithotripters combine ultrasonic and pneumatic lithotripsy to take advantage of the benefits of each.
- Swiss LithoClast uses two independently driven lithotrites combined in one hand piece.
- The CyberWand uses a double-layered probe with a central ultrasonic probe and a passively coupled low-frequency outer probe, which provides ballistic stone fragmentation.
- In vitro and clinical studies showed more efficient stone fragmentation with the CyberWand, although no improvements in stone-free or complication rates have been identified.
- When friable tissues are present or visualization is suboptimal secondary to bleeding or challenging anatomy, single modality lithotripsy should be used. By reducing lithotripsy to ultrasonic only activity and minimizing urothelial contact time, one can reduce the potential for mucosal complications (i.e., bleeding, perforation, future stricture formation).

Other Infections

Urinary tract infections (UTIs) are common, affect men and women of all ages, and vary dramatically in their presentation and sequelae. They are a common cause of morbidity and can lead to significant mortality. Although the urinary tract is normally free of bacterial growth, bacteria that generally ascend from the rectal reservoir may cause UTIs. When bacterial virulence increases or host defense mechanisms decrease, bacterial inoculation, colonization, and infection of the urinary tract occur. Careful diagnosis and treatment result in successful resolution of infections in most instances. A better understanding of the pathogenesis of UTIs and the role of host and bacterial factors has improved the ability to identify patients at risk and prevent or minimize sequelae. Clinical manifestations can vary from asymptomatic bacterial colonization of the bladder to irritative symptoms such as frequency and urgency associated with bacterial infection; upper tract infections associated with fever, chills, and flank pain; and bacteremia associated with severe morbidity, including sepsis and death. New antimicrobial agents that achieve high urinary and tissue levels, can be administered orally, and are not nephrotoxic have significantly reduced the need for hospitalization for severe infection. Shorter-course therapy and prophylactic antimicrobial agents have reduced the morbidity and cost associated with recurrent cystitis in women. Although the vast majority of patients respond promptly and are cured by therapy, early identification and treatment of patients with complicated infections that place them at significant risk remains a clinical challenge to urologists.

DEFINITIONS

UTI is an inflammatory response of the urothelium to bacterial invasion that is usually associated with bacteriuria and pyuria.

Bacteriuria is the presence of bacteria in the urine, which is normally free of bacteria. It has been assumed to be a valid indicator of either bacterial colonization or infection of the

urinary tract. Although this is usually true, studies in animals (Hultgren et al, 1985; Mulvey et al, 1998) and humans (Elliott et al, 1985) have indicated that bacteria may be in the urothelium in the absence of bacteriuria. Alternatively, bacteriuria may represent bacterial contamination of an abacteriuric specimen during collection.

The possibility of contamination increases as the reliability of the collection technique decreases from suprapubic aspiration to catheterization to voided specimens. The term *significant bacteriuria* has a clinical connotation and is used to describe the number of bacteria in a suprapubically aspirated, catheterized, or voided specimen that exceeds the number usually caused by bacterial contamination of the skin, the urethra, or the prepuce or introitus, respectively. Hence it represents a UTI.

Bacteriuria can be *symptomatic* or *asymptomatic*. When it is detected by population studies (screening surveys), *screening bacteriuria* is a more precise and descriptive term than *asymptomatic bacteriuria*, especially because the latter term is clinically useful for describing the presence or absence of symptoms in an individual patient.

Pyuria, the presence of white blood cells (WBCs) in the urine, is generally indicative of infection and/or an inflammatory response of the urothelium to the bacterium, stones, or other indwelling foreign body. Bacteriuria without pyuria is generally indicative of bacterial colonization without infection of the urinary tract. Pyuria without bacteriuria warrants evaluation for tuberculosis, stones, or cancer.

Infections are often defined clinically by their presumed site of origin. *Cystitis* describes a clinical syndrome of dysuria, frequency, urgency, and occasionally suprapubic pain. These symptoms, although generally indicative of bacterial cystitis, may also be associated with infection of the urethra or vagina or noninfectious conditions such as interstitial cystitis, bladder carcinoma, or calculi. Conversely, patients may be asymptomatic and have infection of the bladder and possibly the upper urinary tract.

Acute pyelonephritis is a clinical syndrome of chills, fever, and flank pain that is accompanied by bacteriuria and pyuria, a combination that is reasonably specific for an acute bacterial infection of the kidney. The term should not be used if flank pain is absent. It may have no morphologic or functional components detectable by routine clinical modalities. There may be serious difficulties in diagnosing spinal cord-injured and elderly patients who may be unable to localize the site of their discomfort.

Chronic pyelonephritis describes a shrunken, scarred kidney, diagnosed by morphologic, radiologic, or functional evidence of renal disease that may be postinfectious but is frequently not associated with UTI. Bacterial infection of the kidney may cause a *focal, coarse scar* in the renal cortex overlying a calyx, almost always accompanied by some calyceal distortion (Fig. 12-1), which can be detected radiographically or by gross examination of the kidney. Less commonly, renal scarring from infection can result in atrophic pyelonephritis or generalized thinning of the renal cortex, with a small kidney appearing radiographically similar to one with postobstructive atrophy (Fig. 12-2).

UTIs may also be described in terms of the anatomic or functional status of the urinary tract and the health of the host.

Figure 12-1. Excretory urogram demonstrates focal, coarse scarring in the right kidney of an 18-year-old girl with a history of many recurrent fevers between 2 months and 2 years of age. A cystogram when the patient was 2 years old established an atrophic left kidney with marked reflux up to the left kidney and slight reflux up to the right kidney. Excretory urography at the age of 6 years established severe atrophy of the left kidney. She had no infections between the ages of 6 and 15 years. Several reinfections occurred at the age of 15 years, and they ceased with prophylactic therapy. Her blood pressure has remained normal, and her serum creatinine level was 0.9 mg/dL at the age of 18 years. At 21 years of age she stopped antimicrobial prophylaxis for 18 months without infections or introital colonization with *Enterobacteriaceae*. Note that all calyces are blunted and that one extends to the capsule (arrowhead) because of atrophy of the overlying cortex.

Uncomplicated describes an infection in a healthy patient with a structurally and functionally normal urinary tract. The majority of these patients are women with isolated or recurrent bacterial cystitis or acute pyelonephritis, and the infecting pathogens are usually susceptible to and eradicated by a short course of inexpensive oral antimicrobial therapy.

A **complicated** infection is associated with factors that increase the chance of acquiring bacteria and decrease the efficacy of therapy (Box 12-1). The urinary tract is structurally or functionally abnormal, the host is compromised, and/or the bacteria have increased virulence or antimicrobial resistance. The majority of these patients are men.

Renal diseases that reduce the concentrating ability of the kidney or neurologic conditions that alter bladder-emptying capabilities are commonly encountered functional abnormalities.

Examples of anatomic abnormalities include obstruction associated with calculi or enlargement of the prostate or congenital or acquired sites of residual urine, such as calyceal or bladder diverticula. A complicated infection is frequently caused by bacteria that have exposure to many antimicrobial agents.

Chronic is a poor term that should be avoided in the context of UTIs, except for chronic pyelonephritis or bacterial prostatitis, because the duration of the infection is not defined.

UTIs may also be defined by their relationship to other UTIs:

A **first** or **isolated** infection is one that occurs in an individual who has never had a UTI or has one remote infection from a previous UTI.

An **unresolved** infection is one that has not responded to antimicrobial therapy and is documented to be the same organism with a similar resistance profile.

A **recurrent** infection is one that occurs after documented, successful resolution of an antecedent infection. Consider these two different types of recurrent infection:

1. **Reinfection** describes a new event associated with reintroduction of bacteria into the urinary tract from outside.
2. **Bacterial persistence** refers to a recurrent UTI caused by the same bacteria reemerging from a focus within the urinary tract, such as an infectious stone or the prostate. **Relapse** is frequently used interchangeably. These definitions require careful clinical and bacteriologic assessment and are important because they influence the type and extent of the patient's evaluation and treatment.

Antimicrobial prophylaxis is the prevention of reinfections of the urinary tract by the administration of antimicrobial drugs. If the term is used correctly in reference to the urinary tract, it can be assumed that bacteria have been eliminated before prophylaxis is begun. **Surgical antimicrobial prophylaxis** entails administration of an antimicrobial agent before and for a **limited** time after a procedure to prevent local or systemic postprocedural infections.

Antimicrobial suppression is the prevention of growth of a focus of bacterial persistence that cannot be eradicated. A low, nightly dosage of an antimicrobial agent usually results in the urine showing no growth, as in the case of a stone colonized with bacteria (i.e., infection stone) or in bacterial prostatitis caused by *Escherichia coli*. **Suppressive** is also a useful term when recurrent acute symptoms are prevented in a poor-risk patient, such as one with a large staghorn calculus in whom the antimicrobial agent reduces but does not eliminate the bacteria in the urine.

Domiciliary or **outpatient UTIs** occur in patients who are not hospitalized or institutionalized at the time they become infected. The infections are generally caused by common bowel bacteria (e.g., *Enterobacteriaceae* or *Enterococcus faecalis*) which are susceptible to most antimicrobial agents.

Nosocomial or **health care-associated UTIs** occur in patients who are hospitalized or institutionalized, and these are typically caused by *Pseudomonas* and other more antimicrobial-resistant strains.

Figure 12-2. A, Excretory urogram of the contralateral left kidney from the same patient as in Figure 12-1. The severe pyelonephritic atrophy, undoubtedly caused by febrile urinary infections during early infancy with reflux into different segments of the kidney, produced irregular cortical scarring. Note how all the calyces extend to the capsule with irregular, intervening areas of cortex. B, Pyelonephritic atrophy, suggestive of postobstructive atrophy, in a 20-year-old woman with spina bifida, neurogenic bladder, and many episodes of fever and bacteriuria in early childhood. Observe the uniform, regular atrophy of the renal cortex that suggests reflux of bacteria simultaneously into virtually all nephrons. This type of pyelonephritic atrophy is uncommon compared with that shown in A and is characteristic of obstruction with superimposed infection.

BOX 12-1 Factors That Suggest a Complicated Urinary Tract Infection

Functional or anatomic abnormality of urinary tract
 Male gender
 Pregnancy
 Elderly patient
 Diabetes
 Immunosuppression
 Childhood urinary tract infection
 Recent antimicrobial agent use
 Indwelling urinary catheter
 Urinary tract instrumentation
 Hospital-acquired infection
 Symptoms for more than 7 days at presentation

From Schaeffer AJ. Urinary tract infections. In: Gillenwater JY, Grayhack JT, Howards SS, et al, editors. Adult and pediatric urology. Philadelphia: Lippincott Williams & Wilkins; 2002. p. 212.

KEY POINTS: DEFINITIONS

- Infection of the urinary tract occurs when bacterial virulence increases and/or host defense mechanisms decrease.
- The majority of patients respond promptly to short courses of antimicrobial therapy.
- Early identification and treatment of complicated UTIs is essential to prevent major sequelae or death.

INCIDENCE AND EPIDEMIOLOGY

UTIs are considered to be the most common bacterial infection. They account for more than 7 million visits to physicians' offices and necessitate or complicate over 1 million office visits and 1 million emergency department visits, resulting in 100,000 hospitalizations annually (Patton et al, 1991; Hooton and Stamm, 1997; Foxman 2002). They account for 1.2% of all office visits by women and 0.6% of all office visits by men (Schappert, 1997).

The overall prevalence of bacteriuria in women has been estimated at 3.5%, with prevalence generally increasing with age in a linear trend (Evans et al, 1978). Surveys screening for bacteriuria have shown that about 1% of schoolgirls (aged 5 to 14 years) (Kunin et al, 1962) have bacteriuria and that this figure increases to about 4% by young adulthood and then by an additional 1% to 2% per decade of age (Fig. 12-3). Nearly 30% of women will have had a symptomatic UTI requiring antimicrobial therapy by age 24, and almost half of all women will experience a UTI during their lifetime. The prevalence of bacteriuria in young women is 30 times more than in men. However, with increasing age, the ratio of women to men with bacteriuria progressively decreases. At least 20% of women and 10% of men older than 65 years have bacteriuria (Boscia and Kaye, 1987; Juthani-Mehta, 2007).

The incidence of bacteriuria also increases with institutionalization or hospitalization and concurrent disease (Sourander, 1966). In a study of women and men older than 68 years, Boscia and Kaye (1987) found that 24% of functionally impaired nursing home residents had bacteriuria, compared with 12% of healthy domiciliary subjects (Boscia et al, 1986). UTIs account for approximately 38% of the 2 million nosocomial infections each year (Sedor and Mulholland, 1999; Lo et al, 2008); catheter-associated UTIs (CAUTIs) are the most common nosocomial infection. More than

Figure 12-3. Prevalence of bacteriuria in females as a function of age. (From Stamey TA. The prevention of recurrent urinary infections. New York: Science and Medicine; 1973.)

Figure 12-4. Days between recurrent urinary tract infections grouped by 30-day intervals. (From Kraft JK, Stamey TA. The natural history of symptomatic recurrent bacteriuria in women. *Medicine* 1977;56: 55-60.)

80% of nosocomial UTIs are secondary to an indwelling urethral catheter (Sedor and Mulholland, 1999; Foxman, 2002). The incidence of UTIs is also increased during pregnancy and in patients with spinal cord injuries, diabetes, multiple sclerosis, and human immunodeficiency virus (HIV) infection/acquired immunodeficiency syndrome (AIDS).

The financial impact of community-acquired UTIs is nearly \$1.6 billion in the United States alone (Foxman, 2002); the annual cost of nosocomial UTIs has been estimated to range from between \$515 million and \$548 million (Jarvis, 1996). Each CAUTI is estimated to cost between \$589 and \$758 (Tambyah et al, 2002; Anderson et al, 2007). In patients requiring intensive care, the cost is roughly \$2,000 per nosocomial UTI (Chen et al, 2009).

Little is known about the natural history of untreated bacteriuria in women because most women are treated when they are diagnosed, but a few studies in which treatment with antimicrobial agents is compared with placebo have been done. These show that 57% to 80% of bacteriuric women who are untreated or treated with placebo clear their infections spontaneously (Mabeck, 1972; Guttman, 1973). Mabeck (1972) found that 8 of 53 bacteriuric women placed on placebo needed treatment with an antimicrobial agent because of symptoms, but 32 of the remaining 45 women cleared without treatment within a month, and 43 of the 45 had spontaneously cleared of bacteriuria within 5 months; only 2 women remained persistently bacteriuric.

Once a patient has an infection, he or she is likely to develop subsequent infections. Many adults had UTIs as children, underscoring the importance of genotypic factors in UTIs (Gillenwater et al, 1979). Of 45 women with untreated UTIs whose infection cleared, 20 (46%) had recurrences within a year (Mabeck, 1972).

When women with recurrent bacteriuria were observed after treatment, about one sixth (37 of 219) had a very high recurrence rate (2.6 infections per year), whereas the remaining women had a recurrence rate of only 0.32 per year (Mabeck, 1972). Similar separation was seen in a prospective study, in which only 28.6% of 60 women who experienced their first symptomatic UTI had recurrent infections over the first 18 months of observation, as opposed to recurrences in 82.5% of 106 women who had had previous UTIs (Harrison et al, 1974). Other investigators also have found that the probability of recurrent UTIs increases with the number of previous infections and decreases in inverse proportion to the elapsed time between the first and the second infections (Mabeck, 1972). Of these recurrent infections, 71% to 73% are caused by reinfection with different organisms, rather than recurrence with the same organism (Mabeck, 1972; Guttman, 1973).

Women with frequent reinfections have a rate of 0.13 to 0.25 UTIs per month (1.6 to 3.1 infections per year) when the infections

are treated with antimicrobial agents (Mabeck, 1972; Guttman, 1973; Kraft and Stamey, 1977; Vosti, 2002).

In a prospective long-term study of 235 women with more than 1000 confirmed infections studied over a period ranging from 1 to nearly 20 years, about half of the patients had clusters of infections, which ranged in frequency from 2 to 12 infections per cluster. Infections were followed by remission-free intervals that averaged approximately 1 year. Most reinfections occurred after 2 weeks (Harrison et al, 1974) and within 5 months (Mabeck, 1972), and most occurred early in this interval (Kraft and Stamey, 1977; Vosti, 2002) (Fig. 12-4). Rates of reinfection were independent of bladder dysfunction, radiologic changes of chronic pyelonephritis, and vesicoureteral reflux (Guttman, 1973). The reinfections did not occur evenly over time. In the Stanford series (Kraft and Stamey, 1977), 23 women with frequent recurrent infections were studied with monthly urine cultures when asymptomatic and with immediate cultures when symptomatic for cystitis, for a mean of 3 years. Thirty-four percent of infections were followed by infection-free intervals of at least 6 months (average, 12.8 months), and 22 of the 23 women had such intervals. However, even these long intervals were followed by further infections (Kraft and Stamey, 1977), thus underscoring the importance of genotypic factors in the pathogenesis of UTIs in women (Schaeffer et al, 1981).

When the Stanford data (Kraft and Stamey, 1977) on recurrent UTIs in highly susceptible females is analyzed by examining sets of infections separated by remissions of at least 6 months, 69% of the sets contain only one infection. After this first set, the remaining sets show a 33% remission rate in infections, which means a patient who has two or more infections within 6 months has only a 33% probability of remaining free of infection for the next 6 months. Therefore, if antimicrobial prophylaxis is started after the second or any succeeding infection within a set, about two thirds of the women will benefit.

Whether a patient receives no treatment at all or short-term, long-term, or prophylactic antimicrobial treatment, the risk of recurrent bacteriuria remains the same; prophylactic antimicrobial therapy reduces reinfections but does not alter the underlying predisposition to recurring infection. Asscher and associates (1973) found that reinfections occurred in 17 patients (34%) treated with a 7-day course of nitrofurantoin and in 13 patients (29%) receiving placebo during a 3- to 5-year follow-up. Mabeck (1972) found that 46% (20 of 43) of untreated patients had recurrent infections by 12 months compared with about 40% of treated patients who had recurrences. Both studies suggest that it makes little difference whether a UTI is cured with an antimicrobial agent or is allowed to clear spontaneously—the susceptibility to recurrent UTI remains the same. Moreover, patients with frequent UTI who take prophylactic antimicrobial agents for extended periods (≥ 6

months) may decrease their infections during the time of prophylaxis, but the rate of infection returns to the pretreatment rate after prophylaxis is stopped (Stamm et al, 1980a; Vosti, 1975). Even long interruptions in the pattern of recurrence, therefore, do not appear to alter the patient's basic susceptibility to infections.

The sequelae of complicated UTIs are substantial. It is well established in the presence of obstruction, infection stones, diabetes mellitus, and other risk factors that UTIs in adults can lead to progressive renal damage (Freedman, 1975). The long-term effects of uncomplicated recurrent UTIs are not completely known, but, so far, no association between recurrent infections and renal scarring, hypertension, or progressive renal azotemia has been established (Asscher et al, 1973; Freedman, 1975). Indeed, one investigator was unable to find a single case of unequivocal nonobstructive chronic pyelonephritis in 22 patients in whom chronic pyelonephritis was the cause of end-stage renal failure (Schechter et al, 1971). Similar data were reported by Huland and Busch (1982).

In pregnant women, the prevalence and rate of recurrent infection are the same, but their bacteriuria progresses to acute clinical pyelonephritis more frequently than in nonpregnant women. This variation in the natural history of recurrent infections in females is discussed in a later section on UTIs in pregnancy.

KEY POINTS: INCIDENCE AND EPIDEMIOLOGY

- UTIs are the most common bacterial infection.
- They cause significant morbidity but do not cause renal damage unless comorbidities are present.
- Prophylactic antimicrobial therapy reduces morbidity and the time to recurrent bacteriuria, but the risk of recurrence remains the same.

PATHOGENESIS

UTIs are a result of interactions between the uropathogen and the host. Successful infection of the urinary tract is determined in part by the virulence factors of the bacteria, the inoculum size, and the inadequacy of host defense mechanisms. These factors also play a role in determining the ultimate level of colonization and damage to the urinary tract. Whereas increased bacterial virulence appears to be necessary to overcome strong host resistance, bacteria with minimal virulence factors are able to infect patients who are significantly compromised.

Routes of Infection

Ascending Route

Most bacteria enter the urinary tract from the bowel reservoir via ascent through the urethra into the bladder. Adherence of pathogens to the introital and urothelial mucosa plays a significant role in ascending infections. This route is further enhanced in individuals with significant soiling of the perineum with feces, women who use spermicidal agents (Hooton et al, 1996; Foxman, 2002; Handley et al, 2002), and patients with intermittent or indwelling catheters.

Although cystitis is often restricted to the bladder, approximately 50% of infections can extend into the upper urinary tract (Busch and Huland, 1984). The weight of clinical and experimental evidence strongly suggests that most episodes of pyelonephritis are caused by retrograde ascent of bacteria from the bladder through the ureter to the renal pelvis and parenchyma. Although reflux of urine is probably not required for ascending infections, edema associated with cystitis may cause sufficient changes in the ureterovesical junction to permit reflux. Once the bacteria are introduced into the ureter, they may ascend to the kidney unaided.

However, this ascent would be greatly increased by any process that interferes with the normal ureteral peristaltic function. Gram-negative bacteria and their endotoxins, as well as pregnancy and ureteral obstruction, have a significant antiperistaltic effect.

Bacteria that reach the renal pelvis can enter the renal parenchyma by means of the collecting ducts at the papillary tips and then ascend upward within the collecting tubules. This process is hastened and exacerbated by increased intrapelvic pressure from ureteral obstruction or vesicoureteral reflux, particularly when it is associated with intrarenal reflux.

Hematogenous Route

Infection of the kidney by the hematogenous route is uncommon in normal individuals. However, the kidney is occasionally secondarily infected in patients with *Staphylococcus aureus* bacteremia originating from oral sites or with *Candida fungemia*. Experimental data indicate that infection is enhanced when the kidney is obstructed (Smellie et al, 1975).

Lymphatic Route

Direct extension of bacteria from the adjacent organs via lymphatics may occur in unusual circumstances, such as a severe bowel infection or retroperitoneal abscesses. There is little evidence that lymphatic routes play a significant role in the vast majority of UTIs.

Urinary Pathogens

Most UTIs are caused by facultative anaerobes usually originating from the bowel flora. Uropathogens such as *Staphylococcus epidermidis* and *Candida albicans* originate from the flora of the vagina or perineal skin.

E. coli is by far the most common cause of UTIs, accounting for 85% of community-acquired and 50% of hospital-acquired infections. Other gram-negative Enterobacteriaceae, including *Proteus* and *Klebsiella*, and gram-positive *E. faecalis* and *Staphylococcus saprophyticus* are responsible for the remainder of most community-acquired infections. Nosocomial infections are caused by *E. coli*, *Klebsiella*, *Enterobacter*, *Citrobacter*, *Serratia*, *Pseudomonas aeruginosa*, *Providencia*, *E. faecalis*, and *S. epidermidis* (Kennedy et al, 1965). Less common organisms such as *Gardnerella vaginalis*, *Mycoplasma* species, and *Ureaplasma urealyticum* may infect patients with intermittent or indwelling catheters (Josephson et al, 1988; Fairley and Birch, 1989).

E. coli strains mediating extraintestinal infections are typically grouped into broad phylogenetic classes by multiplex polymerase chain reaction (Clermont et al, 2000), where 70% of uropathogenic *E. coli* (UPEC) isolates fall into the B2 group (Johnson et al, 2001). More recent studies have used multilocus sequence typing to further define and characterize *E. coli* strains mediating UTI and other infections at the level of "sequence type." *E. coli* sequence type ST131 (serotype O25b:H4) merits special attention as a rapidly emerging cause of multidrug-resistant infections, including UTI (Johnson et al, 2010; Kuditinha et al, 2013). Although first noted for extended-spectrum β -lactamases, fluoroquinolone resistance is a hallmark phenotype among ST131 isolates. Recent work with geographically diverse ST131 isolates revealed that a single ST131 subclonal lineage, H30, has emerged within approximately a decade as the major cause of multidrug-resistant *E. coli* infections and is highly associated with recurrent UTI and sepsis (Johnson et al, 2013; Tchesnokova et al, 2013). However, because ST131 isolates were not more virulent in a murine sepsis model, it is likely that the epidemiologic success of ST131 is due to enhanced fitness in early infection events or transmission (Johnson et al, 2012).

The prevalence of infecting organisms is influenced by the patient's age. For example, *S. saprophyticus* is now recognized as causing approximately 10% of symptomatic lower UTIs in young, sexually active females (Latham et al, 1983), whereas it rarely causes infection in males and elderly individuals. A seasonal variation with

a late summer to fall peak has been reported (Hovelius and Mardh, 1984).

Fastidious Organisms

Anaerobes in the Urinary Tract

Although symptomatic anaerobic infections of the urinary tract are documented, they are uncommon. However, the distal urethra, perineum, and vagina are normally colonized by anaerobes. Whereas 1% to 10% of voided urine specimens are positive for anaerobic organisms (Finegold, 1977), anaerobic organisms found in suprapubic aspirates are much more unusual (Gorbach and Bartlett, 1974). Clinically symptomatic UTIs in which only anaerobic organisms are cultured are rare, but these organisms must be suspected when a patient with bladder irritative symptoms has cocci or gram-negative rods seen on microscopic examination of the centrifuged urine (catheterized, suprapubic aspirated, or voided midstream urine) and routine quantitative aerobic cultures fail to grow organisms (Ribot et al, 1981).

Anaerobic organisms are frequently found in suppurative infections of the genitourinary tract. In one study of suppurative genitourinary infections in males, 88% of scrotal, prostatic, and perinephric abscesses included anaerobes among the infecting organisms (Bartlett and Gorbach, 1981). The organisms found are usually *Bacteroides* species, including *B. fragilis*, *Fusobacterium* species, anaerobic cocci, and *Clostridium perfringens* (Finegold, 1977). The growth of clostridia may be associated with cystitis emphysematosa (Bromberg et al, 1982).

Mycobacterium tuberculosis and Other Nontuberculous Mycobacteria

Mycobacterium tuberculosis and other nontuberculous mycobacteria may be found when cultures for acid-fast bacteria are requested; they do not grow under routine aerobic conditions and may be found during evaluation for sterile pyuria. It has been emphasized that the mere presence of mycobacteria may not indicate tissue invasion. Therefore factors such as symptoms, endoscopic or radiologic evidence of infection, abnormal urine sediment, the absence of other pathogens, repeated demonstration of the organism, and the presence of granulomas should be considered before therapy is instituted (Brooker and Aufderheide, 1980; Thomas et al, 1980). (*M. tuberculosis* is discussed in Chapter 17.)

Chlamydia

Chlamydiae are not routinely grown in aerobic culture but have been implicated in genitourinary infections. (Their role in the urinary tract is discussed in Chapter 15.)

Bacterial Virulence Factors

Virulence characteristics play a role in determining both if an organism will invade the urinary tract and the subsequent level of infection within the urinary tract. It is generally believed that uropathogenic strains resident in the bowel flora, such as UPEC, can infect the urinary tract not only by chance but also by the expression of virulence factors that enable them to adhere to and colonize the perineum and urethra and migrate to the urinary tract where they establish an inflammatory response in the urothelium (Schaeffer et al, 1981; Yamamoto et al, 1997; Schlager et al, 2002; Moreno et al, 2008). The same virulence factors can be found on bacterial strains that cause recurrent UTI in patients (Foxman et al, 1995). Some of these virulence determinants are located on one of approximately 20 UPEC-specific pathogenicity-associated islands ranging in size from 30 to 170 kb (Hacker et al, 1999; Oelschlaeger et al, 2002). These pathogenicity islands collectively increase the size of the pathogen genome by about 20% over a commensal strain. A recent genomic analysis of a UPEC

strain revealed the presence of genes for putative chaperone-usher systems, as well as autotransporter proteins that may function as adhesins, toxins, proteases, invasins, serum resistance factors, or motility mediators (Henderson and Nataro, 2001). One UPEC-specific autotransporter, Sat, seems toxic to urinary tract cells in vitro (Guyer et al, 2000) and can cause cytoplasmic vacuolation and severe histologic damage in mouse kidneys (Guyer et al, 2002). Another toxin, hemolysin (HlyA), forms pores in a variety of host cell membranes (Uhlen et al, 2000). In addition to proteases and toxins, UPEC produces several iron acquisition systems, including aerobactin (Johnson et al, 1988; Johnson, 2003) and the more recently described *Iron* system (Russo et al, 1999; Sorsa et al, 2003). Lastly, most UPEC strains produce an acid polysaccharide capsule that protects the bacteria from phagocytosis by human polymorphonuclear leukocytes and inhibits activation of complement (Johnson, 2003).

Early Events in UPEC Pathogenesis

Bacterial Adherence

Bacterial adherence to vaginal and urothelial epithelial cells is an essential step in the initiation of UTIs. This interaction is influenced by the adhesive characteristics of the bacteria, the receptive characteristics of the epithelial surface, and the fluid bathing both surfaces. Bacterial adherence is a specific interaction that plays a role in determining the organism, the host, and the site of infection. Portions of this section on bacterial adherence have been published (Schaeffer et al, 1981).

Bacterial Adhesins. UPEC expresses a number of adhesins that allow it to attach to urinary tract tissues (Mulvey, 2002). These adhesins are classified as either fimbrial or afimbrial, depending on whether the adhesin is displayed as part of a rigid fimbria or pilus (Fig. 12-5). Bacteria may produce a number of antigenically and functionally different pili on the same cell; others produce a single type; in some, no pili are seen (Klemm, 1985). A typical piliated cell may contain 100 to 400 pili. The pilus is usually 5 to 10 nm in diameter, is up to 2 μ m long, and appears to be composed primarily of subunits known as *pilin* (Klemm, 1985). Pili are defined functionally by their ability to mediate hemagglutination of specific types of erythrocytes. The most well-described pili are types 1, P, and S.

Type 1 (Mannose-Sensitive) Pili. Type 1 pili are commonly expressed on both nonpathogenic and pathogenic *E. coli*. Type 1 pili consist of a helical rod composed of repeating FimA subunits joined to a 3-nm wide distal tip structure containing the adhesin FimH (Jones et al, 1995). These pili mediate hemagglutination of guinea pig erythrocytes (Duguid et al, 1979). The reaction is inhibited by the addition of mannose; thus type 1 pili are termed *mannose-sensitive hemagglutination* (MSHA) (Svenson et al, 1984; Reid and Sobel, 1987).

Figure 12-5. Bacterial adherence. Adhesins on pili (fimbriae) mediate attachment to specific epithelial cell receptors.

The role of type 1 pili as a virulence factor in UTIs has been established. This evidence has been obtained (1) from the analysis of bacteria isolated from the urine of patients with UTIs, which were found to express mannose-sensitive (MS) adhesins (Ljungh and Wadstrom, 1983); (2) from studies with animal models (Fader and Davis, 1982; Hagberg et al, 1983a, 1983b; Iwahi et al, 1983; Hultgren et al, 1985) in which inoculation of type 1 pilated organisms into the bladder resulted in significantly more colonization of the urinary tract than inoculation of nonpilated organisms; and (3) from the observation that anti-type 1 pili antibodies and competitive inhibitors such as methyl- α -D-mannopyranoside protected mice from contracting UTIs (Aronson et al, 1979; Hultgren et al, 1985). Recent studies have demonstrated that interactions between FimH and receptors expressed on the luminal surface of the bladder epithelium are critical for the ability of many UPEC strains to colonize the bladder and cause disease (Connell et al, 1996; Langermann et al, 1997; Thankavel et al, 1997; Mulvey et al, 1998).

P (Mannose-Resistant) Pili. P pili confer tropism to the kidney, the designation “P” standing for pyelonephritis (Mulvey, 2002). P pili, which are found in most pyelonephritogenic strains of UPEC, mediate hemagglutination of human erythrocytes that is not altered by mannose and is thus termed *mannose-resistant hemagglutination* (MRHA) (Kallenius et al, 1979). The adhesin PapG, at the tip of the pilus, recognizes the α -D-galactopyranosyl-(1-4)- β -D-galactopyranoside moiety present in the globoseries of glycolipids (Kallenius et al, 1980; Leffler and Svanborg-Eden, 1980), which are found on P blood group antigens and on uroepithelium (Svenson et al, 1983).

The MRHA adhesins of UPEC that do not show the digalactoside-binding specificity have been provisionally named *X adhesins* (Vaisanen et al, 1981). In some strains of UPEC, hemagglutination is mediated by nonpilated adhesins or hemagglutinins (Duguid et al, 1979).

Svanborg-Eden and coworkers (1978) were the first to report a correlation between bacterial adherence and severity of UTIs. They showed that UPEC strains from girls with acute pyelonephritis had high adhesive ability, whereas strains causing asymptomatic bacteriuria or from the feces of healthy girls had low bacterial adherence. Between 70% and 80% of the pyelonephritic strains, but only 10% of the bowel isolates, had adhesive capacity. Furthermore, P pili were present in 91% of urinary strains causing pyelonephritis, 19% of strains causing cystitis, and 14% of strains causing asymptomatic bacteriuria but only 7% of bowel isolates from healthy children, highlighting the correlation between bacterial adherence and UTIs (Kallenius et al, 1981).

Whereas MRHA and P pili are strongly associated with pyelonephritis, these virulence factors are not associated with renal scarring and reflux caused by bacterial infection (Vaisanen et al, 1981). Studies suggest minimal correlation between P-piliated *E. coli* strains and recurrent pyelonephritis with gross reflux in girls (Lomberg et al, 1983). Thus it would appear that P pili in acute pyelonephritis are important mainly in nonrefluxing or minimally refluxing children.

Other Adhesins. S pili, which bind to sialic acid residues via the SfaS adhesin, have been associated with both bladder and kidney infection (Mulvey, 2002). F1C pili bind to glycosphingolipids in renal epithelial cells and induce an interleukin-8 inflammatory response (Backhed et al, 2002).

UPEC also expresses a group of afimbrial adhesins (AFA), which have been clustered with the Dr adhesin family for their recognition of decay-accelerating factor and for their similar genetic structure. Decay-accelerating factor is found on numerous different epithelial sites, and Dr adhesins are known to bind to many locations throughout the urinary tract (Anderson et al, 2004b).

Catch Bonds. Not surprisingly, UPEC adhesins have evolved to meet the physical dynamics of the urinary tract, and this is best understood for FimH. Using hemagglutination assays and flow cell approaches, the affinity of *E. coli* expressing specific FimH alleles for erythrocytes was found to be enhanced by shear stress, and mutations that abolished FimH-erythrocyte interactions in static

conditions did not impact dynamic affinities (Thomas et al, 2002). Conversely, static conditions reduced FimH-erythrocyte interactions. Known as *catch bonds*, this fingertrap-like mechanism is mediated by shear-altered interactions between the FimH pilin and mannose-binding domains that result in force-induced tightening of the mannose-binding pocket (Le Trong et al, 2010). Similar shear-enhanced binding now appears widespread in biology and includes *E. coli* P-fimbriae (reviewed in Sokurenko et al, 2008). The implications of catch bonds for UPEC adherence and UTI pathogenesis are obvious. Enhanced adherence in the presence of shear would promote UPEC retention in the urethra and bladder during voiding and in the ureters against peristalsis. In the absence of shear, reduced FimH affinity would facilitate diffusion and thereby promote ascending infection.

Phase Variation of Bacterial Pili in Vivo

Early evidence for the role of type 1 and P pili in adherence in UTIs in humans was contradictory. Pili were visible by electron microscopy on *E. coli* in the urine of 31 of 37 patients (Ljungh and Wadstrom, 1983). Conversely, no MS adhesins were found in 22 of 24 urine isolates from patients with indwelling catheters (Ofek et al, 1981), and 19 of 20 samples from patients with acute UTIs were devoid of pili and nonadherent until subcultured in broth (Harber et al, 1982). Assessment of pili production by clinical *E. coli* isolates demonstrates that environmental growth conditions can produce rapid changes in pilus expression (Duguid et al, 1966; Goransson and Uhlin, 1984; Hultgren et al, 1986), wherein cells switch back and forth between pilated and nonpilated phases (Eisenstein, 1981). For example, some bacteria grown in a broth medium express pili, whereas the same strain grown on the same medium in a solid state will cease production of pili. This process, called *phase variation*, can also occur in vivo and has obvious biologic and clinical implications. For example, the presence of type 1 pili may be advantageous to the bacteria for adhering to and colonizing the bladder mucosa but disadvantageous because the pili enhance phagocytosis and killing by neutrophils (Silverblatt et al, 1979).
